Table 8.4.7 Relative risks (RR) of health problems associated with obesity

High (RR > 3)	Diabetes, gall bladder disease, dyslipidaemia, insulin resistance, breathlessness, sleep apnoea
Moderate (RR = 2–3)	Ischaemic heart disease, stroke, hypertension, osteoarthritis, hyperuricaemia, gout
Minor (RR = 1–2)	Breast (after the age of 50), colorectal, pancreas, kidney, gall bladder cancers, reproductive hormone abnormalities, polycystic ovary syndrome, impaired fertility, low back pain due to obesity, increased risk of anaesthesia complications, fetal defects associated with maternal obesity, dementia (age 45–59)
New conditions found to be associated with high BMI ^a	Oesophageal cancer, biliary tract cancer, other urinary organ cancers, the aggregate of cardiomyopathy and myocarditis and endocarditis, the aggregate of atrial fibrillation and flutter, pulmonary vascular disease and other cardiovascular disease, chronic kidney disease

^a New conditions based on criteria specified in *The Lancet*, Volume 380, Issue 9859, Lim S. et al., A comparative risk assessment of burden of disease and injury attributable to 67 risk factors and risk factor clusters in 21 regions, 1990–2010: a systematic analysis for the Global Burden of Disease Study 2010, pp. 2224–2260, 2012, Copyright © 2013 Elsevier Ltd All rights reserved.

There are also significant indirect costs to society from obesity due to decreased years of disability-free life, work absenteeism or reduced productivity (presenteeism), disability pensions, increased mortality before retirement, and early retirement. Although individual estimates vary, the magnitude of indirect costs is several times larger than the direct medical costs. For example, obese individuals in Sweden are 1.5–1.9 times more likely to take sick leave, and 12 per cent of obese women had disability pensions attributable to obesity, costing approximately US\$300/year for every woman in the population (Narbro et al. 1996). Among US employees, annual missed workdays increased from 0.5 more days in overweight men to 5.9 more days for men with a BMI of 40 kg/m² or higher (Finkelstein et al. 2009). The annual cost from presenteeism among very obese men amounts to the equivalent of 1 month of lost productivity each year and costs employers US\$3792 per year (Trogdon et al. 2008). Robroek et al. (2011) reported that up to 10 per cent of all sick leave and productivity loss could be attributed to obesity and related life-style behaviours.

Another approach to assessing the impact of obesity and interventions is to use utility values which relate in economic terms to the value a consumer assigns to their own condition or benefit. Both premature mortality and disability together with disability-adjusted life years (DALYs) lost or quality-adjusted life years (QALYs) are considered from national statistics of the prevalence of different medical conditions. The estimations of the DALYs as conducted by the WHO are sometimes considered unusual in that for any other risk factor the challenge was to identify the optimum value to which the average population should ideally strive. For systolic blood pressure the optimum value was estimated to be 115 mmHg and for total blood cholesterol 3.8 mmol/L. These values are very different from what one finds in clinical management guidelines but illustrate the difference between pragmatic clinical judgements and what can be considered ideal from a public health perspective. So the choice of a BMI of 21 as the optimum median population BMI was made in an analogous way based on the handicaps of a higher BMI. The completely new approach introduced by the IHME group from Seattle and Harvard and independently of the WHO (Lim et al. 2012) used huge databases and analyses of multiple studies globally together with many novel assumptions, mathematical simulations, and new dietary analyses to produce totally new results. Only mortality data, mainly from North American and European

databases, were now considered in identifying optimum BMIs of 21–23 and all the risk factors were considered as independent entities even though it is well accepted that weight gain, for example, increases blood cholesterol, blood pressure, and many other risk factors. Tables 8.4.8–8.4.10 illustrate the IHME group's high body mass attributable cause-specific deaths and DALYs respectively and the changes in these indicators between 1990 and 2010. The total number of deaths and DALYs for every cause has risen substantially since 1990 and is especially marked (nearly double) for males.

Ethnic differences in susceptibility to chronic diseases on weight gain

Asian adults who gain weight have a two- to fivefold greater risk for developing type 2 diabetes and hypertension (Fig. 8.4.2) show that both type 2 diabetes and hypertension are markedly amplified by weight gain. Similar relationships have been found in analyses of Mexican national surveys who, like Asians, are more prone to selective abdominal obesity at even normal BMIs than US non-Hispanic white people (Sanchez-Castillo et al. 2005).

Whereas this ethnic difference is often assumed to be genetic, Barker and colleagues suggested a fetal nutrition hypothesis whereby environmental factors both *in utero* and early fetal life amplify the risk of abdominal obesity, diabetes, hypertension, and cardiovascular disease (Barker 2004). Systematic analyses of birth weight and future disease in aboriginal communities in North America and Australasia show a markedly increased risk of type 2 diabetes, poorer kidney function and hypertension, and with pregnancy diabetes strongly associated with metabolic abnormalities and diabetes in the offspring. The links between adverse maternal nutrition and poor infant growth with later hypertension are now evident in both poor and affluent countries (Law et al. 2001). A lower birth weight predicts a higher adult mortality rate, particularly for cardiovascular disease and diabetes with a strong relationship to later cancer in men (Risnes et al. 2011). Indian populations also have a major public health problem of vitamin B₁₂ deficiency which may affect their epigenetic propensity to future non-communicable diseases; pregnant women supplemented with folic acid as well as being vitamin B₁₂ deficient produce offspring which are not only small at birth but fatter, with higher levels of insulin resistance and blood pressure all of which are evident in later childhood (Yajnik et al. 2008). Poor maternal nutrition with low birth weight, maternal smoking, and maternal diabetes all

affect the propensity for obesity in their children, particularly if mothers are overweight/obese with or without gestational diabetes (Fall 2011). The mother's dietary fat intake may also induce a relative increase in their offspring's body fat content through epigenetic changes in the methylation of the promoter regions of the child's genes (Godfrey et al. 2011) and now women are starting pregnancy overweight and producing increasingly heavy babies with a greater propensity to persistent obesity (Gale et al. 2007). The pre-pregnancy size as well as weight gain in pregnancy play important roles in determining greater birth weight and inducing intergenerational obesity. The US Institute of Medicine (2009) has now set out guidelines advocating modest increases in weight during pregnancy.

Projections of the obesity epidemic and its consequent morbidity and costs

Monitoring the changes in the prevalence of obesity and its future occurrence and effects on chronic disease and life expectancy is essential for understanding the challenge and potential benefits of interventions. This applies particularly for children where the health impacts of being obese and overweight will not generally manifest itself until they reach later life.

Conventional analytical methods are generally unable to address satisfactorily situations in which a population's needs change over time. Simulation models combine information from different sources to provide a useful tool for examining how the effects of policies and risk factors unfold over time in complex systems and impact population health. It offers a cheaper and more pragmatic approach than many traditional methods and dynamic models particularly enable alternative scenarios and policies to be tested on specific populations to predict possible outcomes.

There are several methods for modelling the future health outcomes of obesity. Markov cohort models or second-order Markov models simulate a hypothetical cohort of people (Briggs et al. 2006). These cohorts go through a number of health states irrespective of their history. Microsimulations such as that developed for the UK Foresight *Tackling Obesity* enquiry and the OECD chronic disease model track heterogeneous individuals rather than cohorts over time, allowing individual histories to impact on their progression in the model, so microsimulations are able to simulate potential co-morbidities essential to the accurate modelling of chronic diseases. These models show that even small changes in BMI can have a significant impact on avoidable health-care costs over the life course (Wang et al. 2011; Hollingworth et al. 2012). The OECD model has been used to analyse the most cost-effective methods to tackle obesity. Similarly the Australia Cost Effectiveness (ACE) model combines multistate life tables with Markov cohort simulations. Simulation models can provide both a framework for determining future research priorities and support policymakers to make evidence-based decisions (Carter et al. 2008).

Case study

The model developed by the National Heart Forum (UK), now UK Health Forum, for the English Foresight *Tackling Obesity* report is perhaps the most widely applied model having been used to model future trends in obesity and their future consequences for the development of non-communicable diseases in over 70 countries. The microsimulation model simulates a specified number of individuals throughout their lives and takes account of age and subgroup distributions, their probable health consequences, and the potential value of different interventions.

The Foresight report (2007) stimulated the UK government to present the first cross-government strategy to tackle obesity (Department of Health 2008) and similar analyses of all 53 countries of the WHO (Euro) region, regional analysis in Latin America (Webber et al. 2012), the Middle East (Kilpi et al. 2014), Mexico (Rtveladze et al. 2013a), Brazil (Rtveladze et al. 2013b), the Russian Federation (Rtveladze et al. 2012), and the United States (Wang et al. 2011).

These data provide the opportunity to project by non-linear regression analysis the changes in the distribution of BMI by age and sex in the years to come and the potential value of different degrees of intervention at different ages (Fig. 8.4.3). The progressive shift in the distribution of BMI seems unrelenting and the magnitude of the epidemic and its consequences and costs can be predicted with some confidence.

Although the prevention of obesity in children is publicly and therefore politically appealing, it is not likely to bring rapid changes in the population's health and will do little to reduce the escalating health costs of the obesity-induced epidemic of diabetes and hypertension so has a negligible impact on the disease burden over the next 40 years. However, intervention from 18 years onwards brings much earlier and greater benefits so a focus on adults as

well as children is particularly useful for several reasons (Gill 2002; Seidell et al. 2005): the obesity incidence is greatest in early adulthood with further progressive increases and is accompanied by an increasing absolute and population-attributable risk of disease. Parents as adults can also act as models for their children.

Fig. 8.4.3 shows that if the average BMI of the adult population could be reduced by 4 BMI units this would induce a major benefit but this has never been seen except perhaps in Cuba during their financial crisis when food deprivation was widespread. The co-morbidities arise particularly in overweight/obese adults over 50 years, so in terms of cost savings this group could be considered a priority but also those below 50 years who are most vulnerable to developing a co-morbidity, that is, those with pre-diabetes or incipient hypertension. The development of diabetes is particularly sensitive to weight change.

Small errors in energy balance lead to weight increases—the persistence of weight gain

The slimming industry in the United States earns well over US\$100 billion yearly with women spending more than men in their attempts to benefit their health as well as feeling more attractive

after weight loss. This concern may also explain the increase in eating disorders, bulimia, and anorexia nervosa. Yet despite this intense and, in affluent societies, nationwide effort to slim, the obesity epidemic increases with little sign of the impact of all this slimming effort.

The rate of adult weight gain, on average, is 0.5–1.0 kg per year so this amounts to a yearly accumulation of about 3500–7000 kcal. Therefore, the average discrepancy between energy intake and energy expenditure is only 10–20 kcal/day—now called the ‘energy gap’ and only amounts to about 0.4–0.8 per cent of normal food intake per day. This concept of only small average changes in energy storage often leads to the misleading idea that simple small changes—cutting down food a bit and going for a short walk daily—will stop this weight gain.

These small discrepancies actually show how remarkable the normal regulation of energy balance is. Thus our expenditure in all activity may vary daily by 200–300 kcal depending on how much walking or leisure time activity we undertake but the variation in food intake is much more marked and can often vary daily by 1000 kcal. So the discrepancies in energy balance with fat accumulation represent the residual effect of extremely

complex neuro-hormonal regulatory mechanisms operating on a short-, medium-, and long-term basis to preserve energy balance. Unfortunately the mechanisms which avoid weight loss are multiple and much more robust than those which limit weight gain. The bodyweight response to a change of energy intake is normally slow, with half times of about 1 year (Hall et al. 2011). Furthermore, adults with greater adiposity have a larger expected weight loss for the same lower energy intake but to reach their steady-state weight they take longer than it would for those with less initial body fat.

Physical inactivity

The obvious thermodynamic principles of energy balance require the influence of both dietary change and the reduction in physical activity (PA). Cheaper cars for personal transport and multiple mechanical and electrical aids to remove the physical demands in the home and at work have led to a significant reduction in physical exertion. The advent of computers and television mean that in many affluent societies one can earn an excellent wage and have enjoyable leisure without any physical exertion. Children’s habits

are also being transformed by a remarkable secular increase in the time spent watching television or playing video games.

The evidence for current trends in PA varies, but most affluent countries have noted relatively stable rates or slight declines in leisure time physical activity (LTPA) over recent decades (Brownson et al. 2005) and in general the rates of sedentariness, defined as an absence of LTPA, have remained rather stable. Of more importance to total energy expenditure has been the decline in the other domains of PA. The number of people involved in heavy occupational activity has declined dramatically, with more than a 50 per cent reduction in 'heavy work' in Norwegian adults since the middle 1980s, this change being associated with increases in sedentary work (Anderssen et al. 2008). Other countries have noted marked increases in car usage and other motorized transport, at the expense of more active commuting through walking or cycling trips (Fox and Hillsdon 2007). One study even reported a 6 per cent increase in the risk of obesity for every hour spent commuting by car each day (Frank et al. 2004). Limited data are available on domestic settings, but with increases in

technologically sophisticated labour-saving devices, and reduced time spent in preparing meals and carrying out household tasks, it seems that energy expenditure on domestic tasks and yard/garden work is likely to have reduced markedly as well.

The increase in obesity notably in the Netherlands and Scandinavia was delayed by up to a decade, perhaps related to high rates of active commuting, especially cycling, as nutritional differences are not apparent compared with several other western European countries (Select Committee on Health 2006–2007, sections 305–309). A few countries have demonstrated increasing trends in LTPA, for example, in Finland and Canada over the last 25 years and in Singapore over about 10 years (Craig et al. 2004; Barengo et al. 2006). Yet, these countries have increased obesity rates that were similar to demographically matched countries without increases in LTPA (Cutler et al. 2003; Bellanger-Ducharme and Tremblay 2005; Borodulin et al. 2007). In Finnish adults the rates of increases in obesity were also only marginally faster among the inactive and no effects of LTPA levels were evident in Norway. Therefore, the increasing obesity rates develop because of increases in energy intake, or/and from substantial reductions in energy expenditure during the working day.

Recent evidence shows that some individuals spontaneously move more readily than others with a greater increase in spontaneous activity when in positive energy balance; this accounts for about 59 per cent of the variation in fat gain on overfeeding (Levine et al. 1999). This so-called non-exercise activity thermogenesis (NEAT) in part explains the remarkable differences in a highly genetically affected different susceptibility to weight gain on overfeeding (Bouchard et al. 1990). However, the overall societal effects on physical activity are marked as shown by Levine studying rural and urban dwellers in Jamaica and in the United States (Levine et al. 2011). The urban thin adults in both countries had equivalent activity levels but walking and standing was 60 per cent greater in rural than urban Jamaicans. Obese Americans sat for almost 4 hours longer than the rural Jamaicans. Thus there are major societal effects but the genetically susceptible individuals in environments which discourage walking and activity will gain weight first.

A marked transformation of our diets has occurred but measures of energy intakes cannot discern an energy imbalance of 10–20 kcal/day, that is, less than 1 per cent of normal daily intake. Whatever the interplay of changes in intake and energy expenditure under the usual environmental conditions before 1980 children and adults on average maintained their energy balance. So there was sufficient demand for physical work both in the home and in the usual range of occupations for people's appetite regulatory centres to be repeatedly operating to ensure that sufficient but not an excess of food was eaten at that time.

With the removal of the need for physical activity to earn one's living, the biological pressure on people's brain regulatory systems has been to limit intake. In relatively sophisticated environments, the meals and portions served at home and in canteens/restaurants—at least in Europe—have become smaller, presumably in response to consumer demand. National food surveys in the United Kingdom showed a progressive fall in consumption even when allowances were made for the greater amount of food eaten outside the home. Populations have, however, become far more dependent on manufactured processed foods and snacks so energy and nutrient intakes have become dependent on the nature of the purchased food.

Three dietary features have contributed to the obesity epidemic. First is the revolution in the industrial food chain with agricultural policies and subsidies set for the last seven decades on generating ever more and cheaper food. This is now produced in marked excess to human needs in developed countries so the farming and food industries, helped by supermarket developments, have developed methods of persuading the population to purchase and therefore consume as much as possible of this produce. This need to generate profits then led to the second feature which is the intense marketing of products with the discovery that persuading people to have snacks and soft drinks increases sales, particularly if backed by price promotions, large portion sizes, and the ready availability of drinks and food throughout the day in every available location. Then there is the scientific development of food products based on the ready use of different fats, sugars, and salt combinations with additional flavours to trigger defined taste and olfactory responses linked to the pleasure-related neurochemical pathways and brain centres. These changes mean that the energy density of foods in general has increased and this, in double-blind trials, leads to unconscious overconsumption of kilocalories (Prentice and Jebb 2003). Sugar- and perhaps fat-containing foods also trigger pleasure-associated brain dopamine release with new evidence of the probable induction of reduced dopamine receptor activity with a lower dopamine release in the brain centres of those individuals who have become obese (Wang et al. 2012). This implies that more food may be needed by the obese to induce the same dopamine response as observed in lean individuals thereby contributing to the persisting high energy intake in the overweight/obese despite their desire to lose weight. In addition, some investigators now consider that sugar-containing foods trigger insulin resistance and metabolic changes which then promote overeating and even an amplified risk of diabetes (Basu et al. 2013). New meta-analyses show that dietary sugar (and particularly energy-containing sugary drinks) is associated with weight gain (Te Morenga et al. 2012) but this probably operates through an energy density effect on 'passive overconsumption'.

Some research also suggests that chronic stress acts as a risk factor for weight gain. Stress can cause changes to the parasympathetic nervous system, inhibiting satiety and stimulating hunger responses. So individuals exposed to prolonged stress (environmental or psychological) could be more likely to overindulge on so-called comfort foods.

Table 8.4.11 sets out the WHO conclusions (WHO 2003) on the causes of weight gain. WHO has recently concluded that increasing either dietary fat or sugar promote weight gain; the resulting increased energy density is amplified by starch refining and the removal of cellular wall structures which therefore reduces the water containing capacity of the food. These issues have not yet been considered.

The biological as well as societal maintenance of obesity

Unfortunately, there is now good evidence that as weight gain occurs, particularly in older adults, there is a 'resetting' of the regulatory system so weight loss is resisted. Weight gain includes 25 per cent lean tissues which require additional daily energy for their maintenance. Thus people's weight should plateau as soon as their increased weight compensates for the small discrepant intake. Unfortunately this is not as effective as we would

Table 8.4.11 Contributors to the development of obesity as set out by the WHO and categorized by the level of evidence for each contributor

Evidence	Decreases risk	No relationship	Increases risk
Convincing	Regular physical activity High-dietary NSP (fibre) intake		High intake of energy-dense nutrient-poor foods Sedentary lifestyles
Probable	Home and school environments that support healthy food choices for children ^a Promoting linear growth Breastfeeding		Heavy marketing of energy-dense foods ^a and fast-food outlets Adverse social and economic conditions (in developed countries, especially for women) Sugar-sweetened soft drinks and fruit juices
Possible	Low-glycaemic index foods	Protein content of the diet	Large portion sizes High proportion of food prepared outside the home (Western countries) 'Rigid restraint/periodic disinhibition' eating patterns
Insufficient	Increasing eating frequency		Alcohol

^a Associated evidence and expert opinion.

Reproduced with permission from World Health Organization (WHO), *Diet, Nutrition and the Prevention of Chronic Diseases*, Report of a Joint WHO/FAO Expert Consultation, WHO Technical Report Series No. 916, Copyright © WHO 2003, available from http://whqlibdoc.who.int/trs/who_trs_916.pdf.

wish because weight gain usually continues and slowly the neuro-regulatory systems progressively adjust. In due course, the additional 10 kg extra weight then demands a permanent extra daily intake of 200–300 kcal/day. This adaptive mechanism does not occur after the acute overfeeding of young adults because they spontaneously return to their previous body weights but this is not seen when older adults are acutely overfed (Roberts et al. 1994; Roberts and Rosenberg 2006).

Putting overweight and obese individuals on a slimming diet immediately leads to the switching on of acute hormonal, hypothalamic-regulated responses involving both the thyroidal axis and the autonomic nervous system which simulate the response to semi-starvation within 2–4 days even though the obese may have 0.25–1 million extra kcal stored. The brain mechanism which increases the drive to eat is also activated immediately. Whether these mechanisms, traditionally linked to a post-leptin receptor hypothalamic change in responsiveness, are related to the cannabinoid pathways of pleasure highlighted by Volkow and her colleagues (Wang et al. 2012) is unknown. This persistent adaptive change in the brain of obese people helps to induce the regain of weight which they have taken so much trouble to lose. Those who are successful in maintaining their weight loss find that they have to fight a continuous battle for control, following daily and perhaps hourly a rigorous monitoring of their food intake and purchasing habits; they also deliberately engage in 2000–3000 kcal per week of exercise to avoid gaining weight (Wing 2004)! These adaptive problems therefore seem to explain why the obesity epidemic continues to increase despite the desire of so many adults to lose their excess weight. This means that prevention must become a high priority.

Preventive strategies: the options

The analyses presented on the impact of changes in population BMIs at different ages have emphasized the importance of tackling not just obesity but also overweight. Strategies may initially be considered on the basis of rectifying the major societal forces which currently promote the epidemic but the UK Foresight exercise displayed myriad environmental and personal factors not

only affecting food intake and expenditure but where biological effects also interact to determine the propensity to obesity.

The Foresight report made clear that for both physical activity and energy intake there are very powerful environmental forces promoting weight gain that the individual does not control. So obesity was described as a 'passive' normal response of humans to the prevailing inappropriate environment. Personal responsibility plays a crucial part in weight gain but human biology is overwhelmed by the effects of today's 'obesogenic' environment, with its abundance of energy-dense food, motorized transport, and sedentary lifestyles. So the population is inexorably becoming heavier simply by living in their environment. This then means that those who successfully remain lean throughout life are either genetically fortunate or they have the advantage in educative, social, or financial terms to withstand the environmental forces and often create for themselves what is in effect a healthy 'microenvironment'.

Simply abolishing or reversing the obesogenic forces may not be useful prevention strategies. The car, mechanical aids, the computerization of so many processes, and the advent of Internet-related communications have all contributed substantially over the decades to reducing the average cost of physical activity by perhaps 750–1000 kcal/day. Nevertheless reversing these developments as a coherent public health strategy is not an option. So the challenge is how best to combine current understanding of: (1) the most effective initiatives on the basis of either coherent prevention trials or from modelling the underlying processes; (2) the most cost-efficient initiatives; (3) the most feasible initiatives on the basis of the features of the country's societal organization, cultural perceptions, and political system; and (4) whether there are other policy initiatives in the areas affecting food and physical activity which need to be integrated or, if conflicting, resolved. The currently adopted strategies are highly dependent on the political nature of the country ranging from a utilitarian regulatory approach to a more common non-interventionist personal responsibility approach. However, an increasing consensus is emerging about the types of measures needed, as set out in the US Institute of Medicine report (IOM 2012) (Box 8.4.1).

Box 8.4.1 Obesity prevention recommendations and strategies**Integrate physical activity in everyday life**

- ◆ Enhance the physical and built environment.
- ◆ Provide and support community programmes designed to increase physical activity.
- ◆ Provide support for the science and practice of physical activity.

Market what matters for a healthy life

- ◆ Adopt policies and implement practices to reduce overconsumption of sugar-sweetened drinks.
- ◆ Increase the availability of lower-calorie and healthier food and drink options for children in restaurants.
- ◆ Utilize strong nutritional standards for all foods and drinks sold or provided through the government, and ensure that these healthy options are available in all places frequented by the public.
- ◆ Introduce, modify, and utilize health-promoting food and drink retailing and distribution policies.
- ◆ Broaden the examination and development of agriculture policy and research to include implications for the diet.

Make healthy foods and drinks available everywhere

- ◆ Develop and support a sustained, targeted physical activity and nutrition social marketing programme.
- ◆ Implement common standards for marketing foods and drinks to children and adolescents.
- ◆ Ensure consistent nutrition labelling for the front of packages, retail store shelves, and menus and menu boards that encourages healthier food choices.
- ◆ Adopt consistent nutrition education policies for federal programmes with nutrition education components.

Activate employers and healthcare professionals

- ◆ Provide standardized care and advocate for healthy community environments.
- ◆ Ensure coverage of, access to, and incentives for routine obesity prevention, screening, diagnosis, and treatment.
- ◆ Encourage active living and healthy eating at work.
- ◆ Encourage healthy weight gain during pregnancy and breastfeeding, and promote breastfeeding-friendly environments.

Interventions for the prevention of overweight and obesity in school children

- ◆ School-based multicomponent interventions addressing various aspects of diet and/or activity in the school, including the school environment (a 'whole-school approach').
- ◆ Removal of high-fat, high-sugar, and high-salt food and drinks from school environment.
- ◆ Provision of fruit and vegetables and free drinking water.

The WHO set a target of reducing premature mortality from non-communicable diseases by 25 per cent by the year 2025 (WHO 2012a) and for there to be no increase in adult and adolescent overweight and obesity. Oliver Du Schutter, a UN Rapporteur for Food, is more explicit (de Schutter 2012):

Our food systems are making people sick, faced with this public health crisis, we continue to prescribe medical remedies: nutrition pills and early-life nutrition strategies for those lacking in calories; slimming pills, lifestyle advice and calorie counting for the overweight. But we must tackle the systemic problems that generate poor nutrition in all its forms by:

- ◆ taxing unhealthy products;
- ◆ regulating foods high in saturated fats, salt and sugar;
- ◆ cracking down on junk food advertising;
- ◆ overhauling misguided agricultural subsidies that make certain ingredients cheaper than other policies supporting local food

production so that consumers have access to healthy, fresh and nutritious food.

The Lancet series on obesity in 2011 concluded that (Gortmaker et al. 2011):

- ◆ Governments need to lead obesity prevention but few have shown leadership.
- ◆ Empirical evidence of how to prevent obesity is limited but growing: cost-effectiveness policy and programme analyses indicate that several are both effective and cost saving.
- ◆ A systems approach to obesity prevention highlights important policy needs:
 - the need for integrated interventions throughout society with measures by individuals, families, local and national governments and international policy changes

- policies that target the food and built environments
- multiple actions including non-health sectors
- investments in cross-cutting support systems
- the collection of additional data for future forecasts and evaluations of progress.

Age-related issues: childhood prevention

The current focus on childhood overweight/obesity is justified, despite the limited early economic returns (Fig. 8.4.2), on several grounds:

- ◆ Neither the public nor most policymakers blame the individual child for their predicament and only a few try to assign blame to their parents. This childhood focus has a politically useful place in persuading the public and politicians to recognize the importance of environmental rather than individual factors and to do something other than advocating treatment.
- ◆ It is readily recognized that in older children excess weight gain confers on the affected group a far higher medical burden in their lifetime and a much greater probability of an early death than if one simply is concerned about the middle aged and older person.

- ◆ The focus on children also chimes with the routine mantra that the key to the problem of obesity is 'education' so clearly there is merit in educating the child so that they 'do not behave' like their parents.
- ◆ If one is to focus on a group in society then school-aged children is a useful choice because one is guaranteed to be able to reach them in most societies through a school-mediated initiative.

Childhood prevention initiatives

These have been reviewed by Osei-Assibey et al. (2012) who suggested that reducing food promotion to young children, increasing the availability of smaller portions, and providing alternatives to sugar-sweetened soft drinks should be considered but these proposals simply set out the desirable final food changes resulting from suitable prevention schemes and one needs to consider the underlying context.

Approaches to prevention: is there a logic to the chosen initiatives?

A simpler overview than the UK's Foresight collation of different options is presented in Fig. 8.4.4 where the IOTF prevention group highlighted the different environmental systems which affect the environmental impact on both the diet and physical activity.

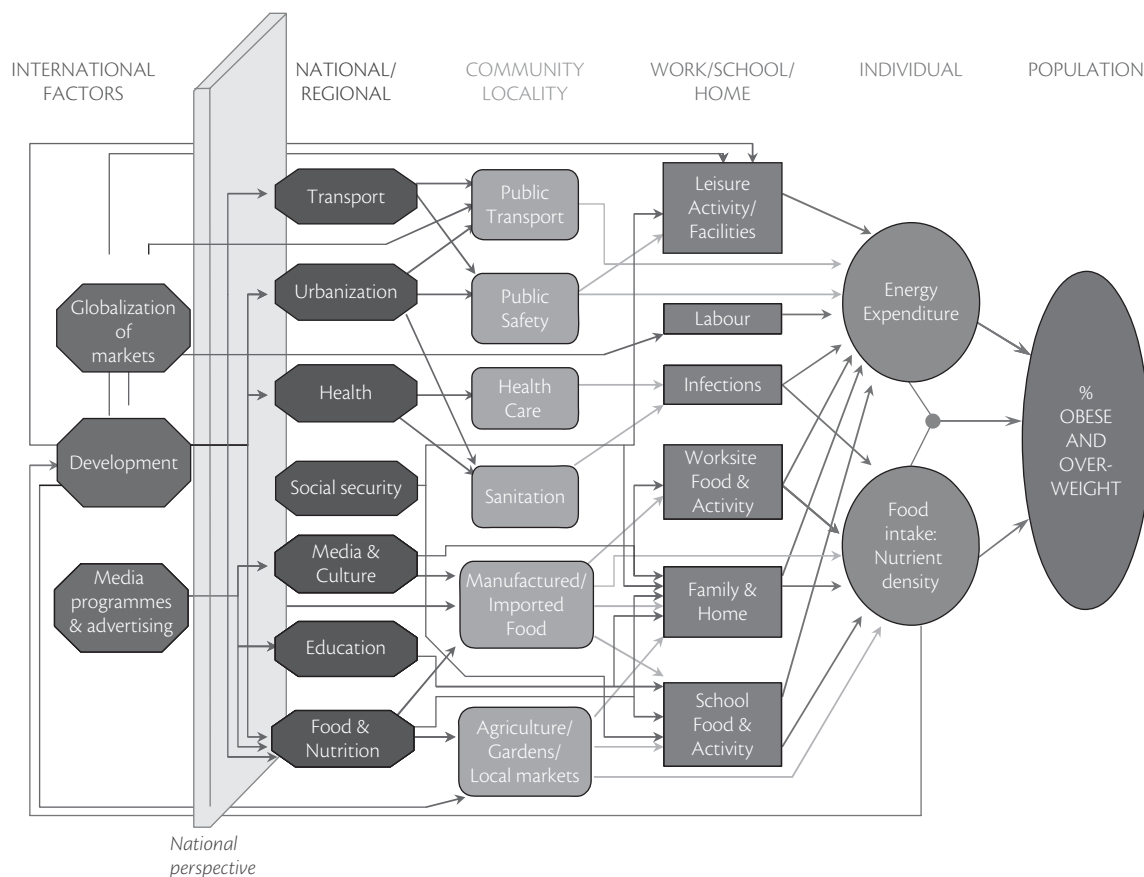

Fig. 8.4.4 Societal policies and processes influencing the population prevalence of obesity.

Public Health Approaches to the Prevention of Obesity (PHAPO) Working Group of the International Obesity Task Force (IOTF). Obesity prevention: the case for action, Copyright © 2002.

Gortmaker et al. (2011) have summarized the prevention options and the ANGELO framework (Egger and Swinburn 1997) has helpfully defined the options both at the micro and macro level in terms of four overall areas of action:

1. Physical changes, for example, in the design of the environment for physical activity involving play areas, safe pedestrian, and cycling-friendly streets or in dietary terms the food availability in shops within easy reach of poor families.
2. Economic, which might involve incentives or taxes or other economic measures at either a local or national level.
3. Political, for example, specifying the requirement for baby-friendly hospitals to promote breastfeeding.
4. Sociocultural, for example, involving changes to the health promotion and other national or local programmes and the involvement of major cultural figures to change perceptions of what is reasonable.

On the energy expenditure side there is concordance between the need to promote physical activity and the demand to limit climate change so national transport systems, for example, trains and the use of buses, need a much higher priority than car use. This then automatically requires more routine walking by the general public. In terms of food, Table 8.4.12 illustrates how the different levels of action can be classified and then how to consider the role of different ministries of government in taking responsibility for these actions.

This approach now allows a logical analysis of the options but still does not necessarily provide a clear approach to the choice of preventive measures.

A systematic review on children's obesity prevention has emphasized the need to integrate community and parental involvement with school-based initiatives (Wang et al. 2013). Integrated analyses of appropriate cost-effective measures have then been set out by Gortmaker et al. (2011) with a number of measures being seen as not only cost-effective but likely to be cost saving once the cost of the intervention and the likely or observed savings in disability costs are compared. In order of priority they listed a 10 per cent tax on unhealthy foods and beverages, traffic light labelling, advertising restrictions of junk food and drinks to children, school-based education to reduce TV viewing, multifaceted diet and activity school initiatives with additional programmes for overweight and obese children, a focus on lowering children's soft drink intake, and family-based programmes for obese children. The intense media-wide marketing of food to children has been shown to induce confusion about nutrition, alter attitudes favouring the advertised goods, change purchasing practices in favour of the foods marketed, and distort the children's diets (Hastings et al. 2003). The additional bonus of a government-directed ban on marketing is that the initiation of these measures simply requires a government regulation which then has to be followed. There is then no cost in terms of educating schools, parents, and children. This illustrates the fact that government intervention using conventional mechanisms for adjusting societal rules or habits usually automatically involve few direct costs. Thus the more that can be undertaken by governmental processes which require industry or businesses or governmental workers to change their practices affecting food and activity, the lower the potential cost compared with individually related initiatives, for example, involving health

education or personal trainers or other focused and individually based advice to individual consumers. However, it is clear that politically one needs to persuade the population through a series of accepted progressive proposals so that politicians are driven to take the progressive steps which several major food industries are lobbying intensely against.

In developing a food business it is well recognized that apart from producing a product that is attractive there are three key features which determine their increasing turnover:

1. The price of their product.
2. Its pervasive availability for consumers.
3. Promotion by intense marketing.

These three factors—price, availability, and marketing—have also been repeatedly shown to be important in the public health initiatives for the effective limiting of smoking and alcohol consumption. The same clearly now applies to the issue of obesity because even children respond to cheaper options by purchasing more, for example, of fruit in a school setting (French et al. 2001). It is also clear that the cost of foods in a Western environment is often inversely related to the nutritional quality of the product; the greater the energy density of the food, that is, in terms of kcal/g then the cheaper it is (Drewnowski and Specter 2004; Maillot et al. 2007). It is therefore not surprising that OECD analyses by health economists show that media campaigns are of no benefit in terms of reducing the disability associated with obesity (Fig. 8.4.5) or the health costs (Fig. 8.4.6). Regulatory and fiscal restrictions as well as an integrated health centre approach to treatment are beneficial rather than just media campaigns which are of little use on their own. Few governments have, however, as yet taken notice of these economic arguments but the evidence is steadily accumulating that, as the current Director General of the WHO, Margaret Chan specifies, we now have to take account not only of Big Tobacco but also of Big Alcohol, Big Food, and Big Soda (Chan 2013). Unless the power and influence of these huge business enterprises are managed, the health costs of the progressively increasing obesity rates are bound to escalate.

The cost of foods in Western environments has been changing steadily over the last six decades as a result of government policies which were set out after the Second World War and led to vast subsidies for both the agriculture and food industries. The aim of the policies was to promote the production and consumption of ever cheaper meat, milk, butter, fats, and oils so that even the poor could afford the originally very expensive meat and butter. However, in responding to their biological desire to satisfy their intrinsic energy needs the poor now purchase the cheapest products which are now rich in fat and sugars. This practice then tends to lead to 'passive overconsumption' because of the relatively poor satiety effects of fats and sugars—the latter particularly when provided in soft drinks between meals. The purchasing patterns of the poorer sections of society are also much more price sensitive; they are spending a much higher proportion of household income on food and normally attempt to minimize these costs to allow more flexibility for purchasing other household needs. Recent 2013 evidence from temporary Danish taxes on saturated fat and French taxes on soft drinks shows that population purchases fall even when there are modest increases in price.

These economic constraints require an integrated approach before satisfactory dietary changes can be supported. Putting a

Table 8.4.12 An update of an approach developed by WHO (Euro) for action by different branches of government on diet and physical activity but taking account of other issues such as food safety and environmental issues

	Dietary quality; physical activity	Food safety	Environment
(A) Ministry of Health—direct responsibilities			
Physical	Appropriately accessible health centres Promoting access to appropriate self-monitoring, e.g. weight, blood pressure	Catering in hospitals; monitoring facilities	Fluoridation systems for water Facilities for iodizing salt
Economic	Primary health payments for specific targets in management	Penalties for providing unsafe food	Subsidize iodine for iodination purposes
Policy	Baby-friendly hospitals Specifying the exclusion of unhealthy foods and drinks from all government premises, e.g. hospitals Dietary guidelines establishing fortification policies Establish policies on health claims, e.g. functional foods	Health impact of multisectoral food safety policies	Establish specific guidelines for toxicants and contaminants in soil, water, and primary food products HIA of agrochemical use
Sociocultural	Health education	Promote concept of limited clinical antibiotic use	Transform economic analyses of traffic policy to account for marked fall in disability from physical activity as well as mortality
(B) Other ministries—but driven by Health Ministry cross-government initiatives			
Physical	Ensuring playgrounds in schools, suitable cycling and road systems; urban planning; sports facilities. Designated urban areas for local food production	Provision of appropriate local abattoirs. Proper public toilet and sanitary facilities. Proper catering facilities based on stringent hygiene requirements	Urban planning: green spaces, cycle paths, parks, playgrounds, lead free Establish facilities for farmers' markets
Economic	Re-evaluate taxation and subsidy policies on food groups; regulatory policies, e.g. all government facilities should serve only healthy foods and drink choices; fast foods, soft drinks etc. excluded. Vegetable costs routinely included in meals in catering/restaurants as in Finland	Establish appropriate penalties for inappropriate hygiene	Reform Common Agricultural Policy (CAP) Finance new public transport systems Promote urban agriculture, new outlets for high-quality, affordable foods in deprived areas
Policy	Health impact assessment of agricultural policies with shift to nutrition sensitive agriculture Food labelling with appropriate, understandable, health-related information, e.g. 'traffic light' labelling Banning + taxing all fast foods and soft drinks as in France Limiting density and siting of fast food outlets in urban areas	Establish criteria for ensuring pathogen- and contaminant-free access to the food chain. Establish systematic HACCP for food chain, systematic surveillance, and mechanisms for emergency response	Reform CAP Develop soil improvement, clean water, agricultural recycling, planting, fertilizer, pesticide, water use policies
Sociocultural	Promote physical activity in the workplace Create breastfeeding time and space in the workplace with non-governmental organization help	Establish new criteria for excluding antibiotics as growth promoters and specifying veterinary use Educational initiatives for safety of fast-food outlets, and modifying nutrient composition, and limiting and ensuring appropriate food waste disposal	Change attitudes to cycle path use, pedestrian areas Educational initiatives for caterers, communal use of school recreational facilities

higher price on fat- and sugar-rich foods is a regressive measure, that is, poorer households will pay more as with taxes on tobacco and alcohol. An integrated economic package therefore needs to be developed so the poorer section of society obtains more financial support by other means. Then the alteration of

relative food prices will still induce changes in the poorer sections of the community as well as in the middle-income group. If appropriate low-energy dense foods are also made readily available, the poorer sections of the community respond. Thus in Finland the cost of vegetables provided with main meals at

canteens and restaurants is included in the general price of the main meal. This benefited the poorer sector of the community and contributed to a trebling in the population's vegetable intake over a 15-year period with a parallel marked reduction in the prevalence of hypertension and a profound fall in cardiovascular diseases.

Conclusions

Prevention policies to reverse the prevalence of obesity are already working for children in several European countries with the most rigorous governmental action being seen in France where new Ministry of Health analyses show a 15 per cent fall in children's overweight and obesity on a national basis. France is also the

country with the most stringent controls on the food and drink industries but as yet there are no studies to show a reversal in adult obesity which is a much bigger challenge. Obesity prevention will require far more rigorous integrated policies from governments who are heavily influenced by the major obesogenic industries which currently resist altering their practices.

Physical activity and health

Nasiha Soofie and Roger Detels

Introduction to physical activity and health

In this chapter we discuss the benefits of physical activity and conversely the harm caused by physical inactivity. We select the term physical activity because it is a behaviour involving action which benefits the individual whereas physical fitness is a condition. Physical activity is defined as any bodily movement produced by skeletal muscle that requires energy expenditure (World Health Organization (WHO) 2013a). Physical inactivity or being sedentary is associated with health risks (Bull et al. 2004). The 1996 Surgeon General's report on physical activity (Howell 1996) emphasized the health benefits of moderate intensity physical activity such as heavy yard work or gardening, brisk walking, housework, as well as leisure time exercise (Macera et al. 2005). Exercise is an important component of a healthy lifestyle, preventing chronic disease and, especially, preventing obesity (Pratt et al. 1999). Despite the well-documented benefits of physical activity, many people do not exercise on a regular basis and prefer a sedentary lifestyle (van der Aa et al. 2010). Hence, the prevalence of obesity in the developed world has substantially increased over the past two decades (Huber et al. 2011). Diabetes mellitus, hypertension, heart disease, cancer, and decreased life expectancies are all associated with obesity with a substantial impact on healthcare costs. Physical inactivity is the fourth leading cause of death worldwide (Kohl et al. 2012). It is estimated that 31 per cent of the world's population is not meeting the minimum recommendations for physical activity (Hallal et al. 2012), and that 6–10 per cent of all deaths from non-communicable diseases worldwide may be attributed to physical inactivity (Lee et al. 2012). In the case of ischaemic heart disease, that percentage increases to 30 per cent (Wen and Wu 2012). If inactivity levels were decreased by 10 per cent or 25 per cent, more than 1.3 million deaths could be averted each year. It is also estimated that the elimination of physical inactivity would increase the life expectancy of the global population by 0.68 years (Lee et al. 2012). Recommendations now generally endorse a minimum level of physical activity of 150 minutes per week (five times 30 minutes) with daily activity. Increased physical activity has been linked to behavioural, social, and physical benefits. Community-based interventions are an important strategy to promote more physical activity (Task Force on Community Preventive Services 2002). These same strategies may also enhance health promotion behaviour worldwide and contribute substantially to reduced healthcare costs and improved quality of life.

According to a WHO global health study conducted across 122 countries representing 88.9 per cent of the world's population,

31.1 per cent of adults are physically inactive (Hallal et al. 2012; Rhodes et al. 2012). The highest level of inactivity was reported for the Americas at 43.2 per cent, with the lowest level at 27.5 per cent in Africa. Women were found to be more inactive (33.9 per cent) than men (27.9 per cent) (Hallal et al. 2012). Physical activity declines with age in all of the WHO regions, resulting in a significant biological deficit (Hallal et al. 2012).

Physical activity levels are generally lower among low socioeconomic groups (Wilson et al. 2004) as a result of both psychosocial and environmental factors (De Cocker et al. 2012). Physical inactivity is also more prevalent in the lower educational groups (Gupta et al. 2012). Physical inactivity is greater in urban areas than in rural areas (Guthold et al. 2008). In summary, one out of five adults around the world is physically inactive. Physical inactivity is shown to be more prevalent among the wealthier and urban countries, as well as among women and older individuals (Dumith et al. 2011).

Definitions and measurements

Physical activity is defined as any bodily movement produced by skeletal muscle that requires energy expenditure (WHO 2013a). This includes physical activity associated with work, travel, domestic activities, and leisure/discretionary activities. While the term physical activity is easily understood, measuring the degree or amount of physical activity is difficult. Physical activity can be measured (Matthews et al. 2012) using a number of strategies or devices, including self-reports, activity diaries, telephone surveys (Mackay et al. 2007), and devices attached to various parts of the body that measure body movements and heart rate, including pedometers, accelerometers, Actiheart®, and the SenseWear® Armband Pro 3 (Bassett 2012), as well as other recently developed technologies. These devices can monitor activity up to 21 days. The International Questionnaire is a recently developed instrument used to assess total activity and time spent in sedentary activities such as watching television, films and computer/Internet activities including texting (Craig et al. 2003). The energy expended doing various activities can be measured under controlled conditions in terms of metabolic equivalents (METs). One MET is the resting metabolic rate at 3.5 mL oxygen/kg (weight)/minute. Daily METs expended can be estimated by multiplying time spent in reported activities by the METs expended as measured in controlled laboratory observations associated with each activity. However, the accuracy of the measurement ultimately depends on the accuracy of the reported time spent in each activity and the reported intensity with which the individual engaged in those activities. The accuracy of the data from the instrument attached to the body for

a limited period can be extrapolated to longer-term and lifestyle estimates. However, it is difficult to establish the reliability and validity of most measures of physical activities. None of the currently available instruments provide precise measures of physical activity over the long term or for population estimates although they may provide an order of magnitude difference that can be correlated to various health outcomes.

Evidence for the benefits of physical activity

Physicians in ancient times, including Hippocrates, circa 400 BC, believed in the value of physical activity to promote health (Lee et al. 2012). Today, it is widely accepted that physical activity is essential in the prevention of chronic diseases and premature death (Inoue et al. 2008; Samitz et al. 2011; Woodcock et al. 2011). A study conducted by Warburton et al. (2006) confirmed that there is strong evidence on the effectiveness of regular physical activity in the primary and secondary prevention of several chronic diseases, including cardiovascular disease, diabetes, cancer, hypertension, obesity, depression, and osteoporosis, as well as for preventing premature death. They were also able to identify a linear relationship between physical activity and health status, such that an increase in physical activity and fitness led to additional improvements in health (Warburton et al. 2006). In addition, there is strong evidence to show that physical inactivity increases the risk of many adverse health conditions, including the major non-communicable diseases such as coronary heart disease and diabetes (Lee et al. 2012). Bull et al. (2004) used various strategies to estimate the attributable burden of disease, and estimated that 20 per cent of the burden of ischaemic heart disease, up to 15 per cent of colon cancer and type 2 diabetes, and 10 per cent of breast cancer and ischaemic stroke were due to physical inactivity (Fig. 8.5.1). Further, they estimated that 5000–7000 lost disability-adjusted life years (DALYs) were attributable to physical inactivity, resulting in ischaemic heart disease, and 1000 DALYs lost, resulting in ischaemic stroke and type 2 diabetes (Fig. 8.5.2) (Bull et al. 2004).

Cardiovascular disease

Sattelmair et al. (2011) reported that individuals who engaged in the equivalent of 150 min/week of moderate-intensity leisure-time

Fig. 8.5.1 Attributable DALYs due to physical inactivity for ischaemic heart disease, ischaemic stroke, type 2 diabetes, and colon and breast cancer. Fig. 8.5.2 Attributable burden of disease due to physical inactivity for ischaemic heart disease, ischaemic stroke, type 2 diabetes, and colon and breast cancer. Reproduced with permission from Bull, F.C. et al., Physical inactivity, in *WHO Comparative Quantification of Health Risk: Global and Regional Burden of Disease Attribution to Selected Major Risk Factors, Volume 1*, World Health Organization, Geneva, Switzerland, Copyright © WHO 2004, available from <http://www.who.int/publications/cra/en/>.

physical activity had a 14 per cent lower coronary heart disease risk compared with those reporting no leisure-time physical activity. Those engaging in the equivalent of 300 min/week of moderate-intensity leisure-time physical activity had a 20 per cent lower risk. At higher levels of physical activity, relative gains were modestly lower. People who were physically active at levels lower than the minimum recommended nonetheless also had significantly lower risk of coronary heart disease. There was a significant interaction by gender ($P = 0.03$); the association being stronger among women than men (Sattelmair et al. 2011). In another study, Sundquist et al. reported that women and men who were physically active at least twice a week had a 41 per cent lower risk of developing coronary heart disease than those who performed no physical activity at all (Sundquist et al. 2004). Li et al. reported that a high level of leisure-time physical activity and moderate level of occupational physical activity have a beneficial effect on cardiovascular health by reducing the overall relative risk of coronary heart disease and stroke among men and women by 20 to 30 per cent and 10 to 20 per cent, respectively (Li et al. 2012).

The benefits of exercise or physical activity in the prevention of cardiovascular disease may be explained from a biological perspective as a boosting of antioxidant levels, epicardial fat reduction, increases in expression of heat-shock proteins and endoplasmic reticulum stress proteins, mitochondrial adaptation, and the role of sarcolemmal and mitochondrial potassium channels. In terms of vascular benefits, the main effects are increases in exercise-induced vascular remodelling and endothelial function. Exercise-induced fibrinolytic and rheological increases also result in haematological benefits (Berlin and Colditz 1990; Golbidi and Laher 2012).

Diabetes

Epidemiological evidence suggests that individuals who maintain a physically active lifestyle are less likely to develop impaired glucose tolerance (Li et al. 2008; Gong et al. 2011; Yoon et al. 2013) and type 2 diabetes mellitus (Dowse et al. 1991; Stern 1991; Ivy 1995; Wylie-Rosett et al. 2006). Exercise also improves many other physiological and metabolic (O'Dea 1984) abnormalities that are associated with type 2 diabetes mellitus by lowering body fat, reducing blood pressure, and reducing dyslipoproteinaemia (Wallberg-Henriksson et al. 1998).

It has also been shown that physical activity may be more effective at managing the symptoms of diabetes compared with medication (Knowler et al. 2002).

Hypertension

Leading national and international professional associations recommend the consistent and long-term implementation of non-drug measures in the treatment of essential hypertension (Institute for Quality and Efficiency in Health Care 2005). So et al. (2013) reported that regular physical activity was positively associated with a lower blood pressure even in non-obese adolescents. Shahraki et al. (2012) found that physical activity reduced arterial blood pressure in female athlete students.

Cancer

Evidence that physical activity is a key modifiable lifestyle risk factor that may reduce the risk of several cancers is now accumulating (James et al. 2011; Na and Oliynyk 2011; Ulrich et al. 2012; Kuijpers et al. 2013; McClellan 2013). The risk of colon, breast (Goh et al. 2012; Guinan et al. 2013; Schmidt et al. 2013), and endometrial (John et al. 2010; Lukowski et al. 2012) cancers is reduced by 25 to 30 per cent in physically active individuals, and evidence for a beneficial effect of physical activity in reducing prostate (Rebillard et al. 2013), ovarian (Olsen et al. 2007; Leitzmann et al. 2009), lung (Emaus et al. 2011; Jones et al. 2012), and other gastrointestinal cancers (Morikawa et al. 2013; Speed-Andrews et al. 2014) is emerging (Aparicio-Ting et al. 2012). There is evidence to suggest that physical activity may alter tumour initiation events by modifying carcinogen activation, specifically by enhancing the cytochrome P450 system and selective enzymes in the carcinogen detoxification pathway. In addition, it may reduce oxidative damage by increasing a variety of antioxidant enzymes, enhancing DNA repair systems and improving intracellular protein repair systems. Physical activity may also exert a cancer-preventive effect by scavenging reactive oxygen species; altering cell proliferation, apoptosis, and differentiation; decreasing inflammation; enhancing immune function and suppressing angiogenesis (Rogers et al. 2008). Physical activity is also associated with a reduction in the psychological and physical symptoms that are associated with both the disease process and treatment (Rajarajeswaran and Vishnupriya 2009).

Osteoporosis

Osteoporosis is characterized by a decline in bone mass with a deterioration of bone tissue, enhanced bone fragility and a consequent increase in fracture risk (Anonymous 1995). As yet, we do not have a complete understanding of how physical activity impacts osteoporosis risk and development. However, there is evidence to suggest that physical activity can help with regulation of bone maintenance (Sinaki 2012), and stimulation of bone formation, as well as with accumulation of minerals, strengthening of muscles (Sinaki et al. 2010), and improving balance, thereby reducing the risk of falls and fractures (Langsetmo et al. 2012). A study by Daly et al. (2008) found that men and women who were more committed to an exercise regimen had lower levels of bone loss and better balance than their less active counterparts. Langsetmo et al. (2012) studied the impact of physical activity on body mass index (BMI) and bone mineral density (BMD) in relation to osteoporosis. The study was conducted on both men and women and found that increased physical activity was related to an increase in

BMD and a decrease in BMI (Daly et al. 2008). Siegrist mentioned two types of physical activity that are important for building and maintaining bone mass and density: (1) weight-bearing exercises, in which bones and muscles work against gravity; and (2) resistance training, using muscular strength to improve muscle mass and strengthen bone (Siegrist 2008). However, further research is needed to elucidate the dose-response relationship between exercise and bone strength, the impact of high-load, high-speed, and impact-type physical training, and the risks and benefits of intensive exercise for elderly individuals with osteoporosis (Suominen 2006).

Mental health

Physical inactivity has been reported to be associated with increased risk of psychological disorders (Careket al. 2011). Conversely, physical activity has also been reported to have beneficial effects in the prevention, treatment, and management of psychiatric disorders (Wolff et al. 2011; Zschucke et al. 2013). It is known that people with depression tend to be less physically active than non-depressed individuals (Teychenne et al. 2008), whereas increasing aerobic exercise and/or strength training has been shown to significantly reduce depressive symptoms (Rimer et al. 2012). Anxiety symptoms and panic disorders also improve with regular exercise (Paluska and Schwenk 2000). Schizophrenic (Bernard and Ninot 2012; Gorczynski and Faulkner 2012; Ter Meulen and de Haan 2012) and bipolar patients (Kucyi et al. 2010) have also reported improvements in health with exercise.

Other

Additional benefits to health include fertility enhancement in reproductive-aged women (Wojtyla et al. 2011), healthier pregnancies (Downs et al. 2012), and improved neonatal outcomes (Ferraro et al. 2012). Physical activity is also associated with improved immune function (Pedersen 1991; Walsh et al. 2011a, 2011b; Wang et al. 2012; Ho et al. 2013) by promoting the activity of natural killer (NK) cells (Pedersen and Ullum 1994) and by increasing the total leucocyte, granulocyte, monocyte, and T-cell counts (Shephard and Shek 1994). Another reported benefit of physical activity involves the nervous system (Carro et al. 2001). Exercise has been reported to have neuroprotective effects to prevent neurological disorders such as multiple sclerosis (Mostert and Kesselring 2002), dementia (Laurinet et al. 2001), and Alzheimer's disease (Kramer and Erickson 2007). Other reports include improvements in the health of the skin (Bates-Jensen et al. 2003), prevention of various disorders such as psoriasis (Anonymous 2012; Frankel et al. 2012), and improvements in functioning of the respiratory (Menezes et al. 2012), renal (Stump 2011), gastrointestinal (Moses 1990; Brouns and Beckers 1993; Peters et al. 2001; de Oliveira and Burini 2009; Martin 2011), and locomotor (Sluka et al. 2013) systems.

Barriers/facilitators of physical activity

Despite widespread and global recognition of the significance of physical inactivity, little progress has been made in improving overall physical activity in the US population (Pratt et al. 2004) or globally. Efforts have been directed at both the individual and group levels. By targeting the community, the possibility of reaching a greater percentage of the underactive population with lower cost per person is potentially increased (King 1998).

A more comprehensive intervention strategy should include personal, interpersonal, institutional, environmental, legislative, and policy levels (King 1998). However, this comprehensive approach must also target land use, the built environment, the public health infrastructure, the safety and design of parks and facilities, and the political process in order to ensure a healthy community.

The choices we make in relation to how we use our land and how we structure our built environment impacts the way we live and move (Powell 2005). This affects the level of physical activity to which an individual is exposed at work and can achieve during leisure time. For example, an apartment block building may be built to encourage the tenants to use the stairs rather than the lift and/or it may have an in-house gym that allows tenants to conveniently engage in a healthier, more active lifestyle. Places of work such as factories, for example, should include exercise facilities which can encourage workers to engage in physical activity during their breaks. Land usage may also be designed to include safe parks equipped with outdoor gyms. These interventions require significant changes in zoning and building code regulations and the attitudes of employers (Powell 2005).

Such changes are not easily achieved, as they involve modifications and support at the community level, and should be consistent with international standards. An understanding of the population, as well as its attitudes regarding the relevance and importance of physical activity, considering age, gender ratios, ethnicity, economic status, and education should be considered prior to planning and implementing an intervention. Planners need to anticipate the need for new policies (Yancey et al. 2007). Planning strategies should include public education, school- and community-based programmes, land use policies and planning, marketing techniques, and federal funding opportunities promoting healthy and fit workplaces (Yancey et al. 2007), as well as safe facilities, particularly in high-crime areas, slums, and rural or remote areas.

Global recommendations on physical activity for health as put forward by the World Health Organization

The WHO recently published guidelines on the recommended levels of physical activity for different age groups. Specifications per age group are stated as follows (WHO 2013b):

- ◆ 5–17-year-olds: 60 minutes of moderate to vigorous intensity physical activity daily.
- ◆ 18–64-year-olds: 150 minutes of moderate intensity activity or 75 minutes of vigorous intensity physical activity per week or an equivalent combination of both.
- ◆ 65 years and older: 150 minutes of moderate intensity activity or 75 minutes of vigorous intensity physical activity per week or an equivalent combination of both. In addition, balance and muscle strengthening exercises are encouraged.

The relationship between diet and physical activity

An effective strategy to control weight and promote health is to adopt and adhere to a healthy eating and fitness regimen (Lloyd-Jones 2009). However, the relationship between the two is sometimes unclear.

Jago et al. studied the relationship between physical activity and diet among African American girls and found that physical activity and fat consumption were inversely related (Jago et al. 2004). Another study by Mattison et al. also found that low levels of leisure time physical activity were consistently associated with a high-fat diet (Mattison et al. 2001). A similar study on the nutritional intake of physically fit and unfit men and women published in 2001 also found that individuals with a higher level of cardiorespiratory fitness were also more likely to follow a diet that was consistent with national dietary recommendations (Brodney et al. 2001).

Sodergren et al. investigated the relationship between fruit and vegetable intake, leisure time physical activity, and sitting time in older adults. They observed that a modest increase in fruit and vegetable intake or leisure-time physical activity had a marked effect on the overall health of older adults (Sodergren et al. 2012). It is reasonable to assume that individuals committed to a fitness regimen of some sort tend to be more health conscious in terms of choice of food (Jago et al. 2004). However, further research into the determinants of lifestyle behaviours are needed (Sodergren et al. 2012).

Behaviour modifications toward a healthier lifestyle should be encouraged by educating the public about healthy food choices, proper interpretation of food labels, and strategies for self-monitoring of diet and physical activity levels. A study of healthy behaviour patterns of individuals who are more successful at adopting a healthy lifestyle may provide additional insight into potential public health strategies to improve the lifestyle of the public (Kruger et al. 2008). Kruger and colleagues reported that dietary practices, dining-out behaviour, and physical activity correlated with weight loss maintenance (Kruger et al. 2008). The study found that men were more successful than women at weight loss maintenance. Individuals who reported eating at a fast-food restaurant two or more times per week were less successful at maintaining healthy behaviour. Sedentary individuals who consumed fewer than five servings of fruit and vegetables per day were less successful in achieving a healthier diet and lifestyle (Kruger et al. 2008). The authors suggested that dining-out behaviours be reduced, and that daily consumption of fruit and vegetables, along with at least 150 minutes of physical activity per week, be encouraged in order to successfully manage weight and adopt a healthier lifestyle (Kruger et al. 2008).

Another study by Kruger et al. found that weighing oneself, keeping track of calories, planning meals, engaging in 30 minutes or more of physical activity per day, as well as leisure-time activities such as cooking and baking were more common in individuals who were successful at maintaining a healthier lifestyle (Kruger et al. 2006).

An important barrier to adopting a healthy diet in slums and for poor individuals is the lack of access to healthy food. Unhealthy foods are often cheaper and thus more affordable. Further, stores selling healthy foods are reluctant to move into high-crime areas. Public health professionals therefore must work with law enforcement agencies to assure security of businesses and residents in slum areas, which will encourage businesses selling healthy foods to operate in such areas and will assure residents that they can engage in jogging and other outdoor physical activities without being subjected to violence.

Strategies for the promotion of physical activity

Children

Health-enhancing physical activity behaviour should be established during the formative years of a child's life (Dobbins et al. 2013), that is, birth to 5 years (Bornstein et al. 2011), so as to reduce the risk of developing self-sabotaging behaviour patterns that are more difficult to address later in life. However, many studies suggest that children in care centres are inactive, with typically high levels of sedentary behaviour (Vasquez et al. 2006). With the increasing number of working women, more children will be placed in care centres. Thus, public health professionals need to target child care centres to promote (mandate) exercise and healthy eating habits. A study conducted by Sugiyama et al. proposed interventions aimed at re-structuring the daycare environment so as to promote physical activity in order to achieve healthy early childhood development and disease prevention (Sugiyama et al. 2012). Furthermore there should be public health policies in place to promote physical activity among the paediatric population, as well as to document the impact of such strategies on motor skills and development (Goldfield et al. 2012).

Adolescents

Adolescents are also known to fail in meeting the required amounts of physical activity. A study focused on enhancing physical activity levels in adolescents suggested a more contemporary approach, that is, the utilization of the Internet to inform and encourage youth to adopt an active lifestyle (Thompson et al. 2012). The rapid expansion and use of the Internet promotes a sedentary lifestyle. Countering this increasing trend promoting a sedentary lifestyle will be difficult. Because the use of the Internet and social media have become so widespread, especially among adolescents and young adults, public health professionals should consider whether the Internet itself can be used to promote a more healthy lifestyle. However, measuring the impact of strategies using the Internet will be difficult.

Neighbourhood 'walkability' has also been suggested as an important predictor of physical activity in Belgian adolescents (De Meester et al. 2012), lending credence to the importance of environment on moulding and establishing behaviour patterns. However, slums often have high crime rates, making walking in them dangerous. Communities and government must come together to make these communities safe for adopting a healthy lifestyle.

A recent school-based approach, GLAMA (Girls!Lead!Achieve! Mentor!Activate), implemented across secondary schools in Australia, was designed to develop leadership skills and school and social connectedness, in addition to a range of physical activity interventions. Activities involved running laps around the school gymnasium and promoting team effort/cooperation that did not require a very high level of motor skill or performance. This study helped highlight feasible strategies to promote physical activity at the school level and encourage students to participate (Jenkinson et al. 2012).

Adults

There have been numerous strategies aimed at increasing the level of physical activity in adults (Haskell et al. 2007). One of the longest running programmes is the 'exercise on prescription' or

EoP programme (Sorensen et al. 2007) that encourages general practitioners (Sorensen et al. 2006; Orrow et al. 2013) to recommend exercise as a prevention and treatment strategy against numerous diseases and illnesses. This programme has been successfully implemented in numerous countries and populations (Gademan et al. 2012) across the world, including South Asian Muslim women (Carroll et al. 2002), Danish communities (Sorensen et al. 2011), South Africa (Dennis and Noakes 1998), and the United States. A similar intervention is the exercise referral scheme (ERS) where inactive individuals are identified within the primary care setting before being referred to a third party for prescribing and supervising an activity regimen. However, this strategy is limited in terms of cost (Anokye et al. 2011). Strategies aimed at easy access to sporting facilities or places of physical activity combined with strategies to increase adult self-efficacy and overcome perceived barriers have also been proposed (Serrano-Sanchez et al. 2012). Another study conducted by Pan et al. (2009) suggested that promotion strategies be tailored to enhance adult confidence levels, to motivate adults to be more active, to educate people on the benefits of physical activity for health, reduce barriers and target different factors appropriate for men and women and for people of different socioeconomic and demographic backgrounds.

The elderly

Although regular physical activity is critical for the promotion of health and function as people get older, they tend to adopt a more sedentary lifestyle (King et al. 1998). Home-based, group-based, and educational physical activity interventions such as telephone calls, incentives, and counselling have been explored, but resulted in physical activity changes that were small and short-lived (Van der Bij et al. 2002).

Physical activity intervention programmes are best kept simple and effective without creating a financial burden on the public health sector (Trueman and Anokye 2013).

Conclusion

Physical activity has been shown to be a key component of a healthy lifestyle that significantly reduces the risk of most non-communicable diseases, promotes mental health, and extends years of healthy, enjoyable life. The current global epidemic of diabetes and overweight is directly attributable to an increasingly sedentary lifestyle associated with the increase of labour-saving devices, passive forms of entertainment (e.g. television), and development of rapid communication modes, as exemplified by the Internet and social media to which many individuals, especially youth, are becoming addicted. The trend in lower levels of physical activity needs to be countered by a vigorous campaign targeting individuals and communities. Communities need to be designed or modified to promote physical exercise. In poor areas and slums, this means assuring the ability to exercise without fear of harm and violence. Successfully promoting a healthy lifestyle incorporating adequate physical activity will require the combined efforts of public health professionals, land use and urban planners, architects and builders, schools, and government, including law enforcement agencies. Physical activity needs to be recognized globally as an essential component of a healthy lifestyle and adopted as a daily routine by all.

Diabetes mellitus

Nigel Unwin and Jonathan Shaw

Definition, classification, and diagnosis of diabetes

Diabetes is a metabolic disease characterized by hyperglycaemia (raised blood glucose) resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association (ADA) 2004). Insulin, produced by the beta cells of the pancreatic islets of Langerhans, is the main hormone regulating blood glucose levels, and is released in response to rising blood glucose following eating or drinking. Insulin has wide-ranging metabolic effects, which include the stimulation of glucose uptake into skeletal muscle and liver, and key roles in lipid and protein metabolism.

Since 1979 and 1980, the ADA and the World Health Organization (WHO), respectively, have produced a series of recommendations on both classification and diagnosis of diabetes. These recommendations have changed over time to reflect the latest scientific evidence. There are small but important differences between the WHO and ADA recommendations. Most parts of the world tend to follow the recommendations of the WHO, but those of the ADA are also followed in many places outside the United States. In the description that follows, we therefore focus on the recommendations of the WHO (2006) but in appropriate places describe how those of the ADA differ.

The classification of diabetes is based on current understandings of its underlying aetiology. There are two main types of diabetes. Type 1 diabetes results from destruction of the insulin-producing cells (beta cells) in the pancreas. This is usually, but not always, associated with detectable auto-antibodies to components of the beta cell, indicating an autoimmune process. Type 2 diabetes, which accounts for 85–95 per cent of all diabetes, results from a combination of resistance to the action of insulin, particularly in skeletal muscle, liver, and fat tissue, and insufficient insulin production by the pancreas. There are several other rarer types of diabetes with specific aetiologies, such as maturity-onset diabetes of the young, associated with specific single-gene defects, and diabetes associated with toxicity to certain drugs. Gestational diabetes refers to diabetes that is diagnosed for the first time during pregnancy. Like type 2 diabetes, gestational diabetes is associated with obesity and a sedentary lifestyle, and it is typically the result of the combination of insulin resistance and insulin secretory defects. Whilst gestational diabetes typically resolves after delivery, a high proportion of women with gestational diabetes develop type 2 diabetes over the next 20 years.

A classification of diabetes is shown in Fig. 8.6.1 (WHO 2006). It is worth remembering that our current understandings of the aetiologies of diabetes remain incomplete, and the classification

described here may well change in the future. The distinction between type 1 and type 2 diabetes is not always clear cut. For example, in adults, diabetes which initially appears to be type 2 diabetes, in that symptoms at presentation are minimal, and there is an adequate initial response to oral therapies, may be accompanied by auto-antibodies to the beta cells. Such cases typically follow a relatively rapid course to insulin dependency, and are essentially a subtype of auto-immune type 1 diabetes in which progression to insulin dependency occurs over months to years, instead of the days to weeks seen in classical type 1 diabetes. This type of diabetes has received various names, including latent auto-immune diabetes of adults (LADA) (Tuomi et al. 1993) and type 1.5 (Palmer and Hirsch 2003).

The relationships between the current aetiological classification and clinical stages of diabetes are shown in Fig. 8.6.1. The clinical staging includes a category called ‘intermediate hyperglycaemia’, in which blood glucose is considered above normal but below the diagnostic thresholds for diabetes. This category should not be considered as a clinical entity but rather as a risk category, identifying people at high risk of developing type 2 diabetes and cardiovascular disease, and providing a potential target for preventive interventions.

Diagnosis

The diagnosis of diabetes has traditionally been based on blood glucose levels, but in the last few years glycated haemoglobin (HbA1c) has been accepted as an alternative. Diagnostic thresholds, following current WHO and ADA recommendations (WHO 2006, 2011; ADA 2013), are shown in Table 8.6.1. The ‘gold standard’ diagnostic test or reference method has been taken to be the oral glucose tolerance test (OGTT). In brief, an OGTT involves the measurement of fasting glucose, followed by a drink containing a fixed quantity of glucose, and the measurement of blood glucose 2 hours after that drink. Undertaking an OGTT is time consuming and relatively expensive (compared to fasting glucose alone). Largely for these pragmatic reasons, the ADA recommends using fasting glucose alone as the main diagnostic test. Unfortunately, however, around one-third of individuals who have diabetes will have an abnormal result after an OGTT but fasting glucose below the diabetes threshold (Decode Study Group 1999). In other words, using fasting glucose alone misses about one-third of individuals with diabetes. Similarly, with fasting glucose, it is impossible to identify those who fall into the category of intermediate hyperglycaemia based on the post-glucose challenge result (impaired glucose tolerance (IGT)), and much of the evidence on preventing type 2 diabetes is in individuals with IGT. There is also good

Stages Types	Normoglycaemia	Hyperglycaemia		
	Normal glucose regulation	Impaired glucose tolerance or Impaired fasting glucose	Diabetes mellitus	
			Not insulin requiring	Insulin requiring for control
				Insulin requiring for survival
Type 1*	←→	←→	←→	←→
Type 2*	←→	←→	←→	←→
Other specific types**	←→	←→	←→	←→
Gestational diabetes**	←→	←→	←→	←→

Fig. 8.6.1 The relationship between aetiological types of diabetes and clinical stages of hyperglycaemia.

* Even after presenting in an acute crisis, such as ketoacidosis, these patients can briefly return to normoglycaemia without requiring specific therapy.

** In rare instances, patients in these categories (e.g. Vacor toxicity, type 1 diabetes presenting in pregnancy) may require insulin for survival.

evidence that the risk of cardiovascular disease associated with raised blood glucose is more strongly related to blood glucose after a glucose load than to fasting glucose (Decode Study Group 2001). It is for all these reasons that the WHO continues to recommend using an OGTT as the main diagnostic test.

The HbA1c offers a simpler approach to the diagnosis of diabetes, since it does not require fasting. HbA1c reflects glycaemic exposure over the prior 3–4 months, and so is also conceptually attractive, as it measures chronic glycaemia, rather than instantaneous blood glucose levels. However, while its place as the key indicator

of glycaemic control among people with diabetes has been secure for many years, it has not been recommended for diagnostic purposes until recently (WHO 2011). The main impediment to its use for diagnosis was concern about variability between laboratories. However, this variability has now been reduced, and it is widely recommended as an alternative diagnostic test. Nevertheless, it is not without its limitations. First, laboratories and assays must be aligned to the international reference values. Second, costs of HbA1c assays are often significantly greater than for blood glucose assays. Third, certain conditions (e.g. haemoglobinopathies, iron deficiency, anaemias, liver and kidney failure) alter red cell turnover, and lead to false lowering or elevation of the HbA1c, making the HbA1c unreliable. Fourth, there is evidence that the relationship between blood glucose levels and HbA1c may be influenced by ethnicity and other factors (Hare et al. 2013), leading to concern that using HbA1c may lead to under-diagnosis or over-diagnosis of diabetes in certain subgroups of the population. It is important to recognize these limitations, and to ensure that HbA1c is only used in situations in which it is both reliable and affordable.

The thresholds for diabetes (Table 8.6.1) are based largely on epidemiological evidence that demonstrates that retinopathy only begins to occur when a certain threshold of glycaemia has been exceeded. This level, or threshold, is apparent for fasting blood glucose, for 2-hour blood glucose (as part of an OGTT) and for HbA1c, and has been taken as the diagnostic value (Colagiuri et al. 2011). It should be noted that such a threshold does not exist for renal complications of diabetes or for cardiovascular disease, partly because the simple measures of these complications (urinary albumin excretion and cardiovascular events) are not specific to diabetes.

Because there is error in laboratory measurements, and there is day-to-day variability in blood glucose levels (less so for HbA1c), the diagnosis of diabetes in someone without symptoms (such as polyuria and polydipsia) should only be made on the basis of two tests on separate occasions. In the presence of symptoms, the

Table 8.6.1 WHO and ADA criteria for the diagnosis of diabetes and intermediate hyperglycaemia in non-pregnant individuals

Diabetes	
Fasting plasma glucose or 2-hour plasma glucose ^a or HbA1c	≥ 7.0 mmol/L (126 mg/dL) or ≥ 11.1 mmol/L (200 mg/dL) or ≥ 6.5% (48 mmol/mol)
Intermediate hyperglycaemia—impaired glucose tolerance (IGT)	
Fasting plasma glucose and 2-hour plasma glucose ^a	< 7.0 mmol/L (126 mg/dL) and 7.8–11.0 mmol/L (140–200 mg/dL)
Intermediate hyperglycaemia—impaired fasting glucose (IFG)	
Fasting plasma glucose and (if measured) 2-hour plasma glucose ^a	6.1–6.9 mmol/L (110–125 mg/dL) and (if measured) < 7.8 mmol/L (140 mg/dL)
Intermediate hyperglycaemia—elevated HbA1c	
HbA1c	6.0–6.4% (42–46 mmol/mol) (WHO) 5.7–6.4% (39–46 mmol/mol) (ADA)

^a Venous plasma glucose 2 hours after ingestion of 75 g oral glucose load (OGTT).

If 2-hour plasma glucose is not measured, status is uncertain as diabetes or IGT cannot be excluded.

diagnosis of diabetes may be based on a single level. It is worth noting that while the diagnostic cut-points for diabetes are of necessity precisely defined (i.e. to the nearest tenth of a mmol/L) different studies suggest somewhat different cut-points often differing by at least 1 mmol/L (Tapp et al. 2006).

The rationale for the cut-points defining intermediate hyperglycaemia is less clear than that for those defining diabetes. Both fasting and 2 hours post-challenge glucose are continuously related to the future risk of diabetes and cardiovascular disease—there is no evidence for thresholds and there is a strong argument for using the actual glucose value as part of a risk score for future diabetes or cardiovascular disease (Unwin et al. 2002; WHO 2006). However, at present, this is not the case. The cut-point for IGT is based on data from the Pima Indians on the risk of incident diabetes (Bennett et al. 1982). Impaired fasting glucose (IFG) was introduced in 1997 by the ADA (The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997), followed by the WHO in 1999 (WHO 1999). The cut-point for IFG proposed in 1997, and still used by the WHO, was based on physiological data of the level above which first phase insulin secretion is lost in response to intravenous glucose (The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 1997). However, in 2003, the ADA recommended a lowering of the cut-point for IFG, based partly on wishing to make the prevalence of IFG more similar to IGT and partly to improve the sensitivity of IFG as a predictor of future diabetes (ADA 2004). The WHO reviewed the classification of intermediate hyperglycaemia in 2006 and decided that the evidence was not strong enough to follow the ADA and lower the IFG cut-point (WHO 2006).

Incidence, prevalence, and trends

The International Diabetes Federation (IDF) produces global estimates of the number of people with diabetes and how their numbers are expected to increase in the future (Whiting et al. 2011). These estimates are mainly based on studies in which blood glucose

was tested and thus include people with diagnosed and undiagnosed diabetes. This is important because in many populations more than half the people with diabetes, sometimes as many as 80 or 90 per cent, have not been diagnosed (Whiting et al. 2011). The age-specific prevalences of diabetes from these epidemiological studies are applied to United Nations population figures and projections, applying as appropriate separate prevalences for urban and rural populations, in order to give national, regional, and global estimates. Many countries, roughly 40 per cent, have not conducted diabetes prevalence studies. For these countries prevalence estimates are based on extrapolation from studies conducted in countries considered similar (Guariguata et al. 2011).

The most recent publication estimated that in 2011 there were 366 million adults globally with diabetes, representing 8.3 per cent of all individuals aged 20–79 years (Whiting et al. 2011). Fig. 8.6.2 shows the prevalence of diabetes in adults across the world. The number of people with diabetes is projected to increase to 552 million by 2030. This estimate is highly conservative as it does not explicitly account for trends in obesity and other risk factors.

The prevalence of diabetes rises steeply with age, but tends to plateau or even fall slightly in those aged 70 years and above. Fig. 8.6.3 shows the prevalence of diabetes by age by World Bank income group. Most people with diabetes, between 85 and 95 per cent depending on the population, have type 2 diabetes. The Global Burden of Disease Study estimates for the prevalence of diabetes (Danaei et al. 2011), which uses a somewhat different methodology, are broadly similar to those of the IDF.

At the present time, it is estimated that between 70 and 80 per cent of people with diabetes live in low- and middle-income countries. This proportion will increase as a result of population growth in developing countries, ageing of their populations, and increasing exposure to risk factors for type 2 diabetes associated with mechanization and urbanization (Unwin 2007). Diabetes, particularly type 2 diabetes, is often thought of as being a disease of affluence, and thus more prevalent in richer

countries. This, however, is a misleading characterization. Upper middle-income countries now have a higher prevalence of diabetes across all adult ages than high-income countries, and lower middle-income countries a higher prevalence up to the age of 60 years (Fig. 8.6.3). Furthermore, it was recently estimated that from 1985 to 2010, the prevalence of diabetes in rural areas of developing countries had approximately quintupled (Hwang et al. 2012).

In high-income countries, the age group with the most cases of diabetes is the 60–79-year-old age group. However, in lower- and middle-income countries, the greatest numbers are aged 40–59. This difference partly reflects younger population age structures in lower- and middle-income countries, but is also partly caused by an earlier age of onset of type 2 diabetes in non-European ethnic groups. The large numbers of working-age adults with diabetes face many years of diabetes, which increases their risk of developing diabetic complications. The economic consequences of significant morbidity during the working years have the potential to cause a significant financial impact on individuals, families, and societies.

Differences in prevalence between population groups

There are large differences in the prevalence of type 2 diabetes between different population groups. For example, in developing countries, the prevalence tends to be several-fold higher in urban compared to rural areas, although as noted earlier this is changing. In most developed countries the highest prevalence and incidence is in those of lowest socioeconomic position (Agardh et al. 2011), with the opposite being described in a number of developing countries, such as China (Xu et al. 2006). It is expected that with further economic development the socioeconomic patterning of type 2 diabetes will be similar in all countries, with the poorest groups having the highest prevalence and incidence (Agardh et al. 2011).

Finally, there are marked differences in diabetes prevalence between some ethnic groups. For example, in England, most studies have found that the prevalence in people of South Asian

Fig. 8.6.4 Estimated prevalence (%) of diabetes by age, sex, and ethnic group in England in 2007.

and African Caribbean origin is two- to fourfold higher than in people of European origin living in the same area (Oldroyd et al. 2005) (see Fig. 8.6.4, based on data from Walker and Unwin (2010)). In North America, African and Hispanic Americans (Kenny et al. 1995) have higher levels of type 2 diabetes than white Americans, with some of the highest rates of all in the indigenous peoples of North America (Gohdes 1995) and Australia (Minges et al. 2011).

Incidence of type 1 diabetes

Unlike type 2 diabetes, in which the incidence is highest in adults and rises with age, the incidence of type 1 diabetes is highest in children, and in most populations peaks between the ages of 5–14 years (IDF 2006). However, it should also be recognized that type 1 diabetes can develop at any age. Internationally there are huge differences, up to 300-fold, in the incidence of type 1 diabetes, with populations originating in Europe having the highest risk. For example, an incidence of greater than 20 per 100 000 per year (in those aged 14 years or less) is found in Finland, Norway, Sweden, and the United Kingdom, and an incidence of less than 1 per 100,000 per year in populations from China and South America (Karvonen et al. 2000). The reasons for these differences are incompletely understood, but the finding that rates tend to increase in migrants from low-incidence to high-incidence areas (Knip et al. 2005) suggests that environmental factors account for at least some of the difference. There is also evidence from several parts of the world, that the incidence of type 1 diabetes is increasing (Derraik et al. 2012; Patterson et al. 2012), particularly in younger children, again suggesting the influence of environmental factors, though the cause of this rise remains very uncertain.

Risk factors and social determinants

There are strong genetic and environmental (in its broadest sense) influences on the risk of both type 1 and type 2 diabetes, and it is the interaction between the two that results in the onset of the disease. The environmental influences on the risk of type 2 diabetes include low levels of physical activity, diets high in saturated fat, salt, and refined carbohydrate, and low in whole grains,

fresh fruit, vegetables, and fibre, calorie excess and obesity, and tobacco exposure. The environmental influences on type 1 diabetes remain frustratingly elusive. In the sections that follow we use the term 'risk factor' to refer to any factor that is associated with an increased incidence of the disease, including those that are markers of early stages of the disease process.

Risk factors for type 1 diabetes

Familial and genetic

The lifetime risk of type 1 diabetes is roughly 6 per cent if a first-degree relative has the condition, such as a sibling, compared to roughly 0.4 per cent (depending on the population) if a first-degree relative is not affected. If a monozygotic twin has type 1 diabetes, the lifetime risk in the other twin is around 50 per cent (Hirschhorn 2003). There are well-established associations between combinations of human leucocyte antigen (HLA) genes and type 1 diabetes. Other genes involved in cell-mediated immunity, and therefore autoimmune disease, have also been associated with type 1 diabetes (Hirschhorn 2003; Gillespie 2006). More than 90 per cent of people with type 1 diabetes carry known genetic markers for the disease (Gillespie 2006). It is important to note, however, that while the presence of known genetic markers greatly increases the risk of the disease, the vast majority people with the genetic markers do not develop type 1 diabetes (Knip et al. 2005).

Environmental factors

The importance of environmental factors is indicated by the changing incidence of type 1 diabetes (described earlier) at a rate that is far too rapid to be due to changes in the gene pool. There is some evidence to implicate viruses, early exposure to cows' milk, and cereals, obesity, and low vitamin D levels, but for none of these is the evidence conclusive (Vehik and Dabelea 2011).

Identifying individuals at high risk of type 1 diabetes

A combination of family history, genotyping, and measurement of auto-antibodies in children aged under 5 can identify a group of individuals who are at very high risk, with 90 per cent or more going on to develop type 1 diabetes (Todd et al. 2011).

Risk factors for type 2 diabetes

It is useful to divide risk factors for type 2 diabetes into unmodifiable and modifiable.

Unmodifiable risk factors for type 2 diabetes

Age and sex

The risk of type 2 diabetes increases steeply with age. Most UK-based studies of previously diagnosed diabetes have found a slightly higher prevalence in men, whereas studies in which glucose is measured either find no sex difference or a slightly higher prevalence in women.

Familial and genetic

The strong familial clustering of type 2 diabetes, suggestive of important genetic influences, has been known for many years (Zimmet 1992). For example, the presence of type 2 diabetes in a parent or sibling approximately doubles the risk of type 2 diabetes. However, identifying genetic markers for type 2 diabetes has proved difficult, and the markers identified to date account for only a few per cent of the genetic risk (Permutt et al. 2005). The reasons for the current lack of success in accounting for the

heritability of type 2 diabetes and other chronic diseases are debated (Eichler et al. 2010). They are likely in part to reflect the (unmeasured) contribution of epigenetic changes to diabetes risk (Drong et al. 2012), discussed briefly later.

Previous gestational diabetes

Women with gestational diabetes tend to be older, more overweight, have a family history of diabetes, and be from an ethnic group with high prevalence of diabetes (Buchanan and Xiang 2005). Following delivery, glucose levels return to normal in around 90 per cent of women, but over the next 10 years, as many as 70 per cent go on to develop diabetes (Buchanan and Xiang 2005).

Ethnicity

As described previously, there are marked differences in the prevalence of type 2 diabetes by ethnic group. It remains far from clear what underlies these differences, how much is related to differences in environment (including behaviours), and how much to differences in genetic susceptibility (Oldroyd et al. 2005).

Modifiable risk factors for type 2 diabetes

Obesity, physical inactivity, aspects of diet, and alcohol

The relationship between overweight and obesity and the risk of type 2 diabetes is continuous, very strong, and is apparent below conventional cut-points for overweight (Vazquez et al. 2007). There is a large body of evidence suggesting that it is the distribution of body fat that is particularly important in determining the risk of type 2 diabetes, with the greatest risk associated with abdominal obesity (Despres 2001).

There is good evidence that physical activity lowers the risk of type 2 diabetes independently of obesity level. Regular moderate or vigorous activity has been associated with a 30–50 per cent reduction in the risk of developing type 2 diabetes (Jeon et al. 2007).

There is also evidence that the composition of the diet, over and above its calorific value, influences the risk of type 2 diabetes. Increased risk has been associated with diets low in fibre and high in saturated fat (Parillo and Riccardi 2004), and conversely intervention studies support the hypothesis that high-fibre, low-saturated-fat diets can help to prevent diabetes (Lindstrom et al. 2006b). High-glycaemic index foods have also been associated with an increased risk of type 2 diabetes (Hodge et al. 2004). Coffee consumption has been consistently associated with a lower risk of type 2 diabetes (van Dam and Hu 2005). Alcohol consumption has a U-shaped relationship with type 2 diabetes incidence, with moderate consumption (20–25 g of alcohol per day) appearing protective in both men and women (Baliunas et al. 2009).

Smoking

Smoking is associated with a dose-dependent increased risk of type 2 diabetes, with former, light, and heavy smokers having a risk of incident type 2 diabetes that is roughly 20, 30, and 60 per cent higher respectively than in those who have never smoked (Willi et al. 2007).

Birth weight, intrauterine environment, and epigenetic changes

There is a U-shaped relationship between birth weight and the risk of type 2 diabetes, and both genetic and environmental factors appear to contribute to this relationship. On the genetic side, for example, there are genetic markers associated with both low

birth weight and an increased risk of diabetes as an adult (Drong et al. 2012). On the environmental side, low birth weight can be the result of poor maternal and therefore fetal nutrition, and high birth weight is linked to maternal obesity and hyperglycaemia (Drong et al. 2012). There is evidence that the impact of adverse fetal environments on the risk of type 2 diabetes carries over into the next generation, for example, the nutritional status of pregnant women can affect the risk of type 2 diabetes in their grandchildren (Drong et al. 2012).

Understanding of the mechanisms through which adverse fetal environments are able to alter gene expression in first- and second-generation offspring is increasing. This is through epigenetic modification of gene expression, which by definition is stable across cell divisions and occurs without change in the primary DNA sequence. Two mechanisms through which this occurs include methylation of DNA, and histone modification (Drong et al. 2012).

The implications of epigenetic gene modification for the future risk of type 2 diabetes are profound. It is plausible, for example, that low birth weight associated with poor fetal nutrition, particularly in rapidly modernizing countries, results in offspring with high rates of adult obesity and type 2 diabetes. This in turn leads to increased numbers of obese women, with hyperglycaemia, leading to higher birth weight offspring again at high risk of type 2 diabetes. Thus, the tendency to type 2 diabetes could become self-reinforcing.

Biological risk factors

There is a continuous positive relationship between blood glucose level (both fasting and post glucose challenge) and the risk of developing type 2 diabetes—the higher the level, the greater the risk (Unwin et al. 2002). As described previously, WHO currently defines two non-diabetic risk categories based on glucose level (see Table 8.6.1): IFG and IGT. The potential benefits of identifying and intervening in people with IGT and IFG are discussed in the section on prevention.

There is a strong tendency for several metabolic and cardiovascular risk factors to cluster within the same individuals. This clustering is strongly associated with abdominal obesity and insulin resistance, and has been labelled ‘the metabolic syndrome’ (Alberti et al. 2007). Core features of the metabolic syndrome include abdominal obesity; raised blood glucose, blood pressure, and triglycerides; and low high-density lipoprotein cholesterol. The presence of the metabolic syndrome in those without diabetes strongly predicts its development (Laaksonen et al. 2002).

Risk scores

Several research groups have derived ‘risk scores’ based on some of the risk factors described earlier in order to help predict who is at high risk of developing type 2 diabetes, and who may then benefit from preventive interventions. A recent systematic review identified ten scores that had been validated in populations external to those for whom they were developed. Overall the scores were shown to discriminate reasonably well between those who will go on to develop type 2 diabetes and those who will not (Buijsse et al. 2011).

Social determinants of diabetes

Any account of risk factors for type 2 diabetes must place the more proximal determinants within the context of the more

distal, social, determinants. It is the broad economic, social, and environmental determinants (discussed in detail elsewhere in this textbook) that shape population levels of physical inactivity, tobacco exposure, alcohol consumption, and unhealthy diet, and which in turn influence the risk and distribution of type 2 diabetes (and related chronic diseases within a population) (Whiting et al. 2010). As discussed in the section on prevention, making substantial progress on reducing the incidence of type 2 diabetes at a population level will require modifying its social determinants.

Health consequences

Mortality and life expectancy

People with diabetes have a substantially higher mortality than people without diabetes, and this is found across all age groups. Overall the relative risk of death is four- to sixfold higher at ages 20–29 years, falls with age but is still 40–80 per cent higher at ages 70–79 years (Roglic and Unwin 2010). In some settings the relative risk of death may be falling, with a recent study from Canada and the United Kingdom finding that between 1996 and 2009, age-adjusted relative risk of death fell from around 2 to around 1.5 (Lind et al. 2013). This might be explained by improved care for people with diabetes, improved case finding increasing the proportion of people with diabetes who are at lower risk at diagnosis, or a combination of the two.

Most, but not all, studies have found that the relative risk of death is higher in women (i.e. compared to women without diabetes) than in men (i.e. compared to men without diabetes). It should be noted that the number of good longitudinal studies able to properly compare mortality rates in people with and without diabetes is relatively small and largely limited to wealthier countries. The relative mortality in poorer countries, where diabetes prevalence is increasing rapidly but where healthcare coverage is often wholly inadequate, may be even greater.

The higher mortality rates in people with diabetes across all age-groups leads to substantial reductions in life expectancy. A UK study estimated that type 2 diabetes at age 40 results in 8 years lost life expectancy in both men and women, and a loss of 4 years at age 60 (Roper et al. 2001). Data on loss of life expectancy in people with type 1 diabetes are harder to find. Widely quoted figures are from a review published in 1984 (Panzram 1984) which found that loss of life expectancy was at least 15 years, whatever the age of diagnosis, with some evidence that it may be over 25 years in those diagnosed under the age of 15. However, a recently published study from Pittsburgh, United States, suggests significant improvements in life expectancy over the past 40 years for people with type 1 diabetes (Miller et al. 2012), but still falling short by around 10 years compared to people without diabetes.

The proportion of deaths attributable to diabetes is not known with accuracy because diabetes is frequently not recorded on death certificates. Estimates of the number of deaths due to diabetes have been made using the relative risk of death in people with diabetes compared to those without, the known prevalence of diabetes and the underlying population mortality. These suggest that globally diabetes is responsible for around 7 per cent of all deaths. In all regions of the world, with the exception of Africa, diabetes is estimated to be responsible in adults for at least one in ten deaths (Roglic and Unwin 2010).

Diabetes-related complications

Diabetes affects multiple organ systems, and complications typically are divided into those affecting large arteries (macrovascular) including those supplying the heart, brain, and lower limbs, and those affecting small vessels (microvascular), including those of the kidney and eye and those supplying the peripheral nervous system. In addition, diabetes is associated with depression, and with liver dysfunction. As noted in later subsections there are some differences in the rate of complications by ethnic group, particularly for coronary heart disease, end-stage renal disease, and lower extremity amputation. The relative contributions to these ethnic group differences of differential healthcare access, behaviours and genetic susceptibility remains incompletely understood (Karter et al. 2002; Lanting et al. 2005).

Cardiovascular disease

The risk of cardiovascular disease in people with diabetes is two- to fourfold higher than in people without diabetes (Stamler et al. 1993; Folsom et al. 1997), and this accounts for much of the increased mortality associated with diabetes (Roglic et al. 2005). In most populations, well over 50 per cent of deaths in people with diabetes are from cardiovascular disease. For example, in people with diabetes in Teesside, England, 59 per cent of deaths in men and 74 per cent in women were due to cardiovascular disease (Roper et al. 2002).

In the United States, people with diabetes of African, Asian (Chinese and Japanese), and Hispanic origin have substantially lower rates of myocardial infarction than those of European origin, and those of the latter two groups lower rates of stroke. Similar findings exist in for people of African origin the United Kingdom (Davis 2008). People with diabetes of South Asian (Indian Asian) origin are at similar or higher risk of cardiovascular disease than those of European origin (Gholap et al. 2011). These differences are not explained by differences in conventional risk factors.

Diabetic eye disease

In developed countries, diabetes is the leading cause of blindness in people aged over 25 years (Klein and Klein 1995). Twenty years after diagnosis, virtually 100 per cent of people with type 1 diabetes have diabetic retinopathy (Klein 1997; Roy et al. 2004), and when blood pressure and blood glucose control are poor, it is estimated that 75 per cent will develop proliferative retinopathy, the most severe form. In type 2 diabetes, between 40 and 60 per cent are expected to develop retinopathy during their lifetime, with around 10 per cent developing proliferative retinopathy (Klein 1997; Eye Diseases Prevalence Research Group et al. 2004). Diabetes also increases the risk of cataracts and open-angle glaucoma (Klein and Klein 1995).

Diabetic renal disease

Diabetes is the leading cause of renal failure in developed countries, responsible for 40–50 per cent of all new patients requiring dialysis in North America, and 15–33 per cent in Europe and Australia (Atkins, 2005). In cross-sectional surveys in Europe, around one in ten people with type 1 diabetes, and one in seven with type 2 diabetes, have evidence of overt nephropathy (IDF 2006). Approximately 30 per cent of people with diabetes with overt nephropathy will progress to end-stage renal failure (Atkins

2005). There are marked differences by ethnic group in the risk of end-stage renal disease, with people of African and Asian origin in particular being at greater risk compared to those of European origin (Karter et al. 2002; Lanting et al. 2005). A high risk of diabetic renal disease has also been described from studies within Asia (Chan et al. 2009).

Neuropathy and diabetic foot problems

The nerve damage associated with diabetes can affect both peripheral and autonomic nerves. Diabetic foot problems are a result of peripheral neuropathy or peripheral vascular disease or a combination of the two (Edmonds et al. 1996). In cross-sectional studies, peripheral neuropathy is found in one in five to more than a third of people with diabetes (IDF 2006). During their lifetime, roughly 15 per cent of people with diabetes develop a foot ulcer and of these 5–15 per cent go on to amputation (Edmonds et al. 1996). In developed countries, diabetes is the single most important cause of non-traumatic lower limb amputation, accounting for 40–60 per cent of all amputations (Global Lower Extremity Amputation Study Group 2000), and people with diabetes have a 15-fold risk of amputation compared to people without diabetes (Edmonds et al. 1996). Differences exist in the risk of lower extremity amputation by ethnic group, with, for example, people of Asian origin in the United States and United Kingdom having a markedly lower risk than the European origin population (Lanting et al. 2005).

Erectile dysfunction

Diabetes increases the risk of erectile dysfunction in men. A large US cohort study (Bacon et al. 2002) found that type 1 diabetes increased the risk threefold, and type 2 diabetes increased the risk by a third. The same study found that the prevalence of erectile dysfunction in men with diabetes was around 50 per cent.

Other co-morbidities

Depressive illness is up to twice as common in people with diabetes than those without (Egede and Ellis, 2010). Depressive symptoms are also a risk factor for type 2 diabetes, associated with roughly a 50 per cent increase in risk (Demakakos et al. 2010). Depression in people with diabetes is associated with more complications and poorer self-care (Lin et al. 2004).

Non-alcoholic fatty liver disease is found in the majority of people with type 2 diabetes (Targher and Byrne, 2013). It is also a risk factor for its development, with some arguing that it is a key part of the pathogenesis (Taylor 2008). In people with diabetes it is strongly associated with the risk of complications, including macrovascular disease and, of course, chronic liver disease (Targher and Byrne 2013).

Finally, there is consistent evidence that diabetes is associated with a 30–40 per cent increased risk of several cancers including of the breast, endometrium, liver, and colon (Chan et al. 2009).

Economic impact of diabetes

Although there is a lack of robust studies into the economic impact of diabetes, it is clear that the cost of diabetes to individuals and their carers, to health services, and to national economies is substantial. On average, a person with diabetes uses more health resources than a person without diabetes—around 1.5–3 times more, depending on age and sex (Zhang et al. 2010). It was

estimated that in 2010 diabetes accounted for between 5 and 15 per cent of health expenditure in over 80 per cent of countries (Zhang et al. 2010). The mean estimated expenditure varies from less than 300 ID (international dollars, adjusted for purchasing power) per person with diabetes per year in most sub-Saharan African countries, to over 3000 ID per year in most of the countries of Western Europe (Zhang et al. 2010). In sub-Saharan Africa diabetes is estimated to be responsible for 3–7 per cent of total health expenditure, and in Europe 9–12 per cent. Diabetes is a substantial cause of health expenditure in several of the poorer countries of Asia, including Bangladesh (10 per cent), India (11 per cent), Thailand (11 per cent), and Sri Lanka (16 per cent). The highest expenditure per person with diabetes by far is in the United States, with a mean expenditure of 7383 ID (Zhang et al. 2010).

At an individual level the costs of diabetes care increase dramatically with the presence of complications, being two- to three-fold higher with the presence of either micro- or macro-vascular complications, and five- to sixfold higher with the presence of both micro- and macrovascular complications than in people with diabetes without complications (Williams 2005). Diabetes, as with any other chronic illness, may limit employment and impact upon the income of people with it and the people caring for them. A study in the United Kingdom found that in people with type 2 diabetes aged less than 65 years, 7 per cent lost income because of diabetes. They lost on average £13,800 per year (at 1998 values) and their carers lost £11,000 per year (Holmes et al. 2003).

The impact of diabetes on gross domestic product (GDP) was estimated for several countries in 2007. The United Kingdom lost 0.4 per cent of GDP, the United States 1.2 per cent, and India 2.1 per cent (Economist Intelligence Unit 2007).

Prevention of diabetes and its complications

Prevention of type 1 diabetes

As noted earlier, it is possible to identify individuals based on auto-antibodies, family history, and genetic background, at very high risk of developing type 1 diabetes. This is a costly and labour-intensive exercise, but has been done as part of evaluating preventive measures in such individuals. Unfortunately none of the measures for prevention so far tested have been found to work (Gillespie 2006; Todd et al. 2011). Furthermore true primary prevention requires approaches that prevent the onset of the auto-immune process. How to prevent type 1 diabetes remains an area under active investigation (Todd et al. 2011).

Prevention of type 2 diabetes

Targeting individuals at high risk

There is excellent evidence that type 2 diabetes can be prevented, or at least its onset delayed, in individuals at high risk of type 2 diabetes, such as those with impaired glucose tolerance and/or fasting hyperglycaemia. Interventions aimed at modifying behaviours and pharmacological interventions have both been shown to be effective, and at best to reduce the incidence of type 2 diabetes by 50–60 per cent. Aspects of behavioural change that were promoted in these trials included weight loss (in those overweight and obese), increased physical activity, and a diet low in total and saturated fat and high in fibre. The more behavioural goals

that are achieved, the lower the long-term risk of type 2 diabetes (Lindstrom et al. 2006a). Based on the results of the trials, the number needed to treat to prevent one case of type 2 diabetes by behavioural interventions is around 6–7 over 3–5 years, and using oral diabetes drugs is 10–11 (Gillies et al. 2007).

While undoubtedly new approaches to the prevention of diabetes in those at high risk will be trialled, particularly additional pharmacological agents, a major challenge is how to translate the results from well-resourced trials into everyday healthcare and community settings. A recent review identified 17 translational studies, 14 of which were carried out in the United States (Johnson et al. 2013). Individuals at high risk of type 2 diabetes were identified in several ways, including the use of risk scores. The findings of the studies are encouraging in that all but one reported greater weight loss in the intervention compared to the control arm, but there were no consistent differences in glucose or waist circumference. Clearly more work, in a greater variety of geographical settings, is required to assess the feasibility and cost-effectiveness of approaches targeting individuals at high risk of type 2 diabetes.

Population-wide approaches

Targeting individuals at high risk of diabetes is unlikely to have a large impact on the overall population incidence of type 2 diabetes, since 40–60 per cent of new cases of type 2 diabetes arise in people who had normal glucose tolerance 3–5 years earlier (Unwin et al. 2002). It is only through population-based measures aimed at reducing overweight and obesity and increasing physical activity that a large impact on the incidence of type 2 diabetes will be achieved. The potential impact of population-wide measures was illustrated in an analysis from the EPIC-Norfolk cohort. It assessed the association between the achievement of five ‘diabetes healthy behaviour prevention goals’ (BMI < 25 kg/m², fat intake < 30 per cent of energy intake, saturated fat intake < 10 per cent of energy intake, fibre intake 15 g/1000 kcal, physical activity 4 hours/week). If the entire population were able to meet one more goal, the total incidence of diabetes would be predicted to fall by 20 per cent (Simmons et al. 2006).

As reviewed elsewhere in this textbook, achieving population-wide changes to reduce the incidence of diabetes and related chronic non-communicable diseases (NCDs) presents major challenges. The 2011 United Nations High Level Meeting on chronic NCDs strongly recognized the need for legislative, fiscal, and other policy measures. These measures need to involve all sectors of government, civic society, and, as appropriate, the private sector, in order to start to change environments from being ‘obesogenic’ (Egger and Swinburn 1997) towards those that promote healthier diets and physical activity. The challenge of achieving this is clear when it is appreciated that despite increasing awareness in many parts of the world amongst both policymakers and the general public on the detrimental effects of obesity, there is not yet a single population-wide example where the trend towards increasing levels of obesity has been reversed. Presumably, it is in recognition of this challenge that of the nine voluntary NCD targets adopted by the World Health Assembly in 2013, that for obesity and diabetes is for no change (a 0 per cent increase) by 2025. Even that, however, may prove overly optimistic given current trends.

Policy measures aimed at the prevention of type 2 diabetes and related NCDs will need to address the fact that these conditions

tend to be socially distributed, with highest risks in the less well educated and poorer parts of the population. Interventions need to be carefully designed and evaluated to reduce inequities in outcomes between social groups.

Prevention of diabetes-related complications

While primary prevention of diabetes is the ultimate goal, there is excellent evidence that the increased morbidity and mortality in people with diabetes, compared to those without, can be significantly reduced. Some of the healthcare interventions are highly cost-effective (Table 8.6.2) (Venkat Narayan et al. 2006). Control of blood glucose, blood pressure, blood lipids, and the avoidance of smoking are core; with specific measures to reduce the incidence of sight-threatening retinopathy, morbidity and loss of the lower limbs, and progression to end-stage renal disease. The core measures overlap completely, of course, with those recommended for people at high risk of cardiovascular disease events (Mendis et al. 2011).

Given the existence of these highly effective interventions, and the fact that at diagnosis up to 50 per cent or more of people with type 2 diabetes have evidence of microvascular complications (Spijkerman et al. 2003), there is strong interest in early detection or screening. Indeed, a substantial proportion of people with type 2 diabetes are undiagnosed, particularly in low- and middle-income countries: estimated to be 50–60 per cent in the Middle East and North Africa, 50 per cent in South East Asia, and 60 per cent in the Western Pacific (Whiting et al. 2011). Although randomized controlled evidence for the benefits of the screening for type 2 diabetes is lacking, there is nonetheless a clear rationale for it, supported by studies modelling its impact on macro- and microvascular outcomes (Khunti and Davies 2012). The feasibility and cost-effectiveness of different approaches to earlier detection of type 2 diabetes will depend on the setting, and most crucially the ability of the health system to absorb and deliver effective treatment to increased numbers of people with diabetes (Glumer et al. 2006). In many situations, particularly those with limited resources, it is beneficial to target diagnostic blood glucose testing only on

those individuals who are at high risk of having undiagnosed diabetes. Many risk scores, with reasonable sensitivity and specificity, have been developed to identify individuals for blood glucose testing (Brown et al. 2012). These can be used opportunistically and as part of a mass screening programme. Few of these scores, however, have been evaluated in low- or middle-income settings (Brown et al. 2012).

A detailed discussion of how to achieve reductions in morbidity and mortality in people with diabetes and the contents of good diabetes care is beyond the scope of this chapter. There are many sources of guidance on this, including the Global Guideline for Type 2 diabetes from the IDF (IDF: Clinical Guidelines Taskforce 2012). However, it is worth making the following points here. People with diabetes play the central role in managing their condition (as with most chronic conditions), and thus core to effective diabetes care is empowering people with diabetes with the knowledge and support they need to do this. Effective healthcare for diabetes, in common with many other chronic conditions (Epping-Jordan et al. 2004), requires a well-functioning health-care system, with good communication between many different specialities and levels of care. Finally, it is an accurate generalization to state that diabetes care is currently suboptimal the world over (Venkat Narayan et al. 2006), in both rich and poor countries. In rich countries, suboptimal care includes inadequate coverage of basic preventive measures, such as regular eye and foot examinations, as well as room for much better control of glucose, blood pressure, and lipids. In poor countries, inadequate care includes no care at all for a large proportion of people with diabetes, including, in many parts of the world, lack of, or intermittent access to, insulin leading to the death of those who require it for survival (Yudkin 2000).

It is not hyperbole to state that diabetes presents one of the major public health challenges of the twenty-first century. In response to this, the United Nations General Assembly in 2006 passed a resolution calling for coordinated global action on diabetes (Unite for Diabetes 2006) and endorsing 14 November, the birthday of Frederick Banting, one of the discoverers of insulin, as World Diabetes Day.

Table 8.6.2 Examples of treatment strategies and relative reductions in morbidity and mortality in people with diabetes

Strategy	Estimated benefit
Glycaemic control in people with HbA1c > 9 per cent	Reduction of 30 per cent in microvascular disease per 1 per cent drop in HbA1c
Glycaemic control in people with HbA1c > 8 per cent	Reduction of 30 per cent in microvascular disease per 1 per cent drop in HbA1c
Blood pressure control in people whose pressure is higher than 160/95 mmHg	Reduction of 35 per cent in macrovascular and microvascular disease per 10 mmHg drop in blood pressure
Cholesterol control in people with total cholesterol < 5.2 mmol/L	Reduction of 25–55 per cent in coronary heart diseases events; 43 per cent fall in death rate
Annual screening for microalbuminuria	Reduction of 50 per cent in nephropathy using ACE inhibitors for identified cases
Annual eye examinations	Reduction of 60 to 70 per cent in serious vision loss
Foot care in people with high risk of ulcers	Reduction of 50 to 60 per cent in serious foot disease
Aspirin use in people with established cardiovascular disease	Reduction of 28 per cent in myocardial infarctions, reduction of 18 per cent in cardiovascular disease
ACE inhibitor use in all people with diabetes	Reduction of 42 per cent in nephropathy; 22 per cent reduction in cardiovascular disease

Public mental health and suicide

Kristian Wahlbeck and Danuta Wasserman

Introduction to public mental health and suicide

As defined by the World Health Organization (WHO), mental health is not just the absence of illness, rather it is conceptualized as a state of well-being in which the individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community (WHO 2013). Consequently, public mental health is not just about the occurrence and prevention of mental disorders in the population, but it also concerns the promotion of mental health and well-being. Thus, public mental health can be defined as actions aimed at developing the mental health of populations and producing healthy societies.

Public mental health research encompasses research that describes collective experience, occurrence, distribution and trajectories of positive mental health, mental health problems, and their determinants; research on mental health promotion and prevention of mental disorders; research on mental health system policies and governance; service delivery; and the organization of mental health services.

Mental health is more crucial today than it has ever been, due to the societal transition into the information society era. The population's mental capital (i.e. cognitive, emotional, and social-skills resources required for role functioning) is a prerequisite for the prosperity of individuals, companies, and societies in this new era. Mental health becomes more valuable and more vulnerable, due to the many stressors in information-driven economies. At the same time, in low-income countries, poverty, discrimination, and poor mental health form a vicious circle which becomes an obstacle to economic development (Patel and Thornicroft 2009).

The huge burden and costs of impaired mental health for individuals, families, society, and the economy call for actions to prevent mental ill health and promote positive mental health and well-being. This necessitates public mental health actions, not only to treat, but also to prevent impaired mental health and promote positive mental well-being.

Magnitude and costs of mental health problems

The magnitude and costs of mental health and mental disorders is relatively neglected (Jané-Llopis et al. 2011), in spite of data

showing that mental health is a growing health challenge. The share of burden attributable to mental and behavioural disorders, which is already substantial, will probably increase steadily in the future. The rising burden from mental and behavioural disorders will impose new challenges on health systems worldwide.

The recent update of the Global Burden of Diseases study (Murray et al. 2012) demonstrates the magnitude of the burden of mental health disorders. Disability-adjusted life years (DALYs) include potential years of life lost, due to premature death and equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. DALY data indicate that mental disorders constitute a growing share of the global disease burden. In 2010, mental and behavioural disorders accounted for 7.4 per cent of DALYs worldwide, which is a significant increase from 1990, when the corresponding figure was 5.4 per cent. A single major source of disability and premature death is major depressive disorder (MDD). From 1990 to 2010, MDD increased in ranking from 15th to 11th place (i.e. a 37 per cent increase) among causes of DALYs worldwide. In order of importance, other main causes of DALYs among mental disorders were anxiety disorders (1.1 per cent of DALYs worldwide), drug use disorders (0.8 per cent), alcohol use disorders (0.7 per cent), and schizophrenia (0.6 per cent) (Murray et al. 2012). Self-harm, which in 2010 ranked number 18 among worldwide causes of DALYs, adds to the total impact of mental and behavioural disorders on population health.

The distribution of DALYs varies considerably between geographical regions. The relative contribution of mental and behavioural disorders is as a rule higher in developed economies. According to the Global Burden of Diseases study, mental disorders accounted for 11 per cent of the total burden of illness in high-income regions, such as Australasia, Europe, and North America. In many highly developed Western economies, up to half of the disability pensions are granted due to mental disorders, especially depression. It is, thus, foreseeable that a continued increase in the standard of living globally will contribute to a continued epidemiological transition towards increasing public health impact of mental disorders. In many of the developed economies, MDD ranks 3rd, 4th, or 5th among causes of DALYs (Murray et al. 2012). In regions with high suicide mortality rates, such as Eastern Europe, Japan, and South Korea, self-harm ranks 5th or 6th among causes of DALYs.

The disabling burden of mental and behavioural disorders is almost the same for males and females, but the major contributing

causes are different. The burden of depression is 50 per cent higher for females than males. In contrast, the occurrence of alcohol and drug use disorders in males is nearly seven times higher than that for females, and accounts for almost one third of the male burden of mental and behavioural disorders. In both low- and middle-income countries, and high-income countries, alcohol use disorders are among the ten leading causes of years lived with disability (YLD). This includes only the direct burden of alcohol dependence and problem use. The total attributable burden of disability, due to alcohol use, is much larger.

The Millennium Development Goals (MDGs) primarily target childhood mortality and communicable diseases. The epidemiological shift from communicable diseases towards non-communicable psychosocial disorders constitutes a global health challenge. When setting the post-2015 development goals, promotion of population mental health is important, as mental health has vast and global well-being consequences. The WHO Action Plan 2013–2020 on mental health, approved by Member States at the WHO World Health Assembly, is a milestone in acknowledging the importance of mental health and the well-being of entire populations (WHO 2013).

Available data confirm the immense disability burden of mental disorders, not only in terms of DALYs, but also in terms of other indicators, such as loss of work days, work life productivity, and poor quality of life (Wittchen et al. 2011). This is due to the critical combination of high prevalence and high level of associated impairments and disabilities of mental disorders. Many mental disorders—anxiety, substance use, and somatoform disorders in particular—start early, which typically has adverse effects on further psychological and social development, thereby reducing school and academic achievement, social functioning, and social integration.

Compared to many somatic diseases, costs for mental disorders differ with disproportionately high indirect cost items (e.g. sick days, disability, early retirement, and deaths due to suicide) and relatively low direct costs of healthcare (i.e. low expenditures for diagnostic measures, treatment, and care). Mental disorders are dominant contributors to the global economic burden of diseases. The global cost of mental health conditions in 2010 was estimated at US\$2.5 trillion, with the cost projected to surge to US\$6 trillion by 2030. About two-thirds of the total cost comes from indirect costs, and the remainder from direct costs. Currently, high-income countries shoulder about 65 per cent of the burden, which is not expected to change over the next 20 years (Bloom et al. 2011).

For instance, in Europe, depressive disorder is a major cause of lost productivity (Wahlbeck 2009). In 2004, economic costs of depression were estimated to be €250 per inhabitant, or €118 billion. As mentioned earlier, direct costs account for only a minor part of the total economic burden (Sobocki et al. 2006). A majority of costs, between 65 and 85 per cent, are indirect. Data from Europe indicate that costs for depression are increasing (Sobocki et al. 2007).

People with mental disorders, including substance use disorders, are at risk of suicide. Ninety per cent of suicides are estimated to be associated with mental disorders, mostly with mood disorders, like depression, which is associated with 60 per cent of suicides (Mann et al. 2005) and also with alcohol use disorders. However, suicide is not a disease caused by well-defined pathological mechanisms,

and the occurrence of suicidal behaviour is usually an outcome of complex interactions of socioenvironmental, behavioural, and psychiatric factors. High-risk groups include those with severe somatic illness, the socially disadvantaged, those with recent loss, especially through suicide (Nordentoft 2007), and some migrant groups (Garssen et al. 2006; Westman et al. 2006). People with a history of suicide attempts are especially at higher risk of dying by suicide.

According to WHO data, suicides (i.e. deaths caused from self-inflicted intentional injuries) amounted to 782,000 in 2008, which was 1.4 per cent of the total world mortality, ranging from 0.5 per cent in the African region to 1.9 per cent in the South-East Asian region (Värnik 2012). However, the WHO estimate includes neither injury deaths of undetermined intent nor deaths from unknown causes, which are generally believed to conceal unrecognized suicides. Moreover, the data from all WHO member states are not reported.

The estimated global suicide rate is 14 suicides per 100,000 inhabitants, including 18 suicides per 100,000 for males and 11 suicides per 100,000 for females. For both males and females, the highest suicide rates are found in Europe, predominantly in Eastern Europe, that is, Lithuania, the Russian Federation, Belarus and, to a lesser extent, Finland, Hungary, and Latvia: a group of countries that share similar historical and sociocultural characteristics, as well as similar alcohol use patterns. Nevertheless, some similarly high rates are found in countries that are quite distinct in relation to these characteristics, such as Cuba, Japan, Sri Lanka, and South Korea. As a whole, the lowest rates are found in Islamic countries (Bertolote and Fleischmann 2009). Due to stigmatization and legal sanctions against suicide, underreporting of suicide rates in Muslim countries may partly contribute to the low suicide mortality rates reported (Khan and Syed 2011).

The male suicide rate is higher than the rate of females, with the exception of youth suicide rates in some Asian countries, where the sex differences for suicide are reversed, and young women are more at risk for suicide than men, mainly due to impulsive attempts using pesticides as the mode of attempt (Law and Liu 2008).

Suicide in later life is a global public health problem. Those aged 65 years and above are the demographic group that constitutes the highest suicide rate in most countries reporting suicide statistics to the WHO. Non-fatal suicidal acts tend to be less common in this age group (Fässberg et al. 2012).

The epidemiology of adolescent suicide has shown striking changes over the last 100 years, with a steady decline in recent decades. One of the suggested factors explaining this trend is the growing use of antidepressants, especially selective serotonin reuptake inhibitors, in the adolescent population (Bursztein and Apter 2009). Even within countries, there is significant variability in suicidal ideation and behaviours among adolescents of different ethnic backgrounds. In the United States, American Indian/Alaska Native youth tend to have the highest rates of fatal suicidal behaviour among all ethnic groups. There are similar findings for Inuit populations in Canada, and the Ethiopian population in Israel, with regards to fatal suicide. All of these youth show a similar pattern of failure to integrate traditional cultures with a modern Western culture (Amitai and Apter 2012).

Suicide rates are higher in many disadvantaged populations groups, such as ethnic or sexual minorities. Family rejection

or negative family reaction to an adolescent who is gay, lesbian, or bisexual is associated with an eightfold greater likelihood of attempting suicide compared to adolescents who experienced minimal or no family rejection (Ryan et al. 2009). The suicide risk of gay and lesbian youth is amendable; lesbian and gay youths living in areas with school anti-bullying policies that did not specifically mention sexual orientation as a protected group were nearly two times more likely to have attempted suicide in the past year compared with those living in counties where more districts had these policies (Hatzenbuehler and Keyes 2013).

A highly increased risk of suicide after a suicide attempt can be found in people with a mental disorder. To reduce risk of attempting further suicides, people with mental disorders need after-care, especially during the first 2 years after the suicide attempt (Tidemalm et al. 2008).

During the last 50 years, the epicentre of suicide mortality has moved eastwards from Western Europe to Eastern Europe and now to Asia. The biggest contributors to the number of suicides in the world are China and India, where half of the total suicides in the world occur, while South Korea has experienced enormous growth in suicide rates during the past decade (Vijayakumar 2004; Värnik 2012).

Mental health policy

In spite of their public health impact, mental health issues were largely neglected in the international public health agenda until the 1990s. In order to successfully introduce mental health issues on the political agenda during that time, a new approach has been developed in Europe. It has been stressed that mental health cannot be reduced to an issue about mental disorders. Neither the high prevalence of mental disorders, nor the need for more resources in psychiatry was used as entry points, thus, avoiding the stigma associated with mental disorders. Instead, it has been stressed that mental health is an indivisible part of public health, and that it has a significant impact on countries and their human, social and economic capital. The aim has been to raise mental health from its professional, organizational, and even political isolation to a broader sphere of public health, that is, to shift the focus from the individual level towards strengthening the mental health approach at the population level. Acknowledging the psychosocial determinants of mental health opens the door for horizontal actions to promote population mental health (Wahlbeck 2011b).

It is now widely accepted that major mental health determinants are modifiable by policy actions. During the last decades, many governments and intergovernmental organizations have developed mental health policies, as a response to increasing mental health needs in the population. Typical objectives of the policies are increased parity between mental and physical disorders, reduction of stigma, respect for human rights, a shift from hospital-based to community-based service provision and strengthening of mental healthcare capacity in primary care.

The lessons of the successful control of infectious and cardiovascular diseases indicate that the road to improved mental health among populations lies not in the investment of mental health services, but in promotion and prevention activities. Thus, lately many policy documents have taken the 'Health in All Policies' (HiAP) approach, that is, targeting determinants of mental health

across policy areas in the whole population, reaching out to public policymakers to mainstream mental health promotion and prevention of mental health problems in non-health policies. HiAP is a relatively new approach to the development, implementation, and assessment of public policies across sectors that systematically take into account the health implications of decisions. It can be seen as a strategy to recognize that mental health is largely constructed in other sectors than in the health sector (Wahlbeck and Taipale 2006).

The stigma associated with mental disorders may have a negative impact on the willingness of decision-makers to commit to a high-level mental health policy. A clear public health approach, and making mental health promotion one of the core objectives, will highlight the productivity links of mental health, and offers a route to successfully avoiding the stigma and discrimination attached to mental health issues.

Mental disorders are inextricably linked to human rights issues. The stigma, discrimination, and human rights violations that individuals and families affected by mental disorders suffer are intense and pervasive. Most international mental health policy documents build on the human rights principles and stress the need for respectful treatment and empowerment of mental health service users. The United Nations Convention on the Rights of People with Disabilities (CRPD), adopted in 2006, affirms that people with mental health disabilities have the right to full participation and inclusion in society, including the right to live independently, the right to education, and the right to work. The CRPD, and related pressure from the international community, will increasingly put human and fundamental rights issues at the forefront of new regional and national mental health policies across the globe.

In May 2013, the WHO World Health Assembly approved the first WHO action plan on mental health, covering the period from 2013 to 2020 (WHO 2013). The plan's four major objectives are to: strengthen effective leadership and governance for mental health; provide comprehensive, integrated, and responsive mental health and social care services in community-based settings; implement strategies for promotion and prevention in mental health; and strengthen information systems, evidence, and research for mental health. The plan sets new directions for mental health, including a central role for provision of community-based care, and a greater emphasis on human rights. It also emphasizes the empowerment of people with mental disabilities, the need to develop strong civil society, and implement health promotion and prevention activities. The document proposes specific actions for Member States, the WHO, and partners. It also proposes indicators and targets, such as a 20 per cent increase in service coverage for severe mental disorders, and a 10 per cent reduction of the suicide rate in countries by the year 2020, which can be used to evaluate levels of implementation, progress, and impact.

Setting mental health targets in policy action plans may help focus attention and support implementation. Targets should, however, be formulated as health inequality targets to support mental health improvement and suicide reduction among the most vulnerable groups or in the most deprived areas. To be meaningful, measurement of targets should avoid masking deterioration in one segment of the population by an improvement in another segment (e.g. an increase of suicides in young people by a decrease in older people) (Wahlbeck 2009).

Stigma and public attitudes

People with mental health problems have to cope with a double problem: first, the symptoms of the mental health problem, and second, with the stigma of having a mental health problem (Rüsch et al. 2005). Stigma is a core concept in understanding the field of public mental health and provision of health services. Stigma has an in-depth influence on the status of mental health services, their resource allocation and attractiveness to the work force. It constitutes a barrier that greatly contributes to low help-seeking behaviour among people with mental health problems, and affects provision of services negatively.

Stigma and stereotypes form the public attitude towards people with mental health problems and psychiatry. Stigma related to mental health problems can be divided into: (1) perceived public stigma, that is, stereotype awareness; (2) personal stigma, that is, stereotype agreement (people's personal beliefs about mental illness); and (3) self-stigma (people's view of their own mental health problem) (Rüsch et al. 2005). Discrimination of people with mental disorders is a common manifestation of stigma.

Stigma studies across the world have generally shown consistent findings. There is a lack of parity between mental and physical disorders; people with mental disorders, as well as the services they are provided, are less valued. This is extremely unfortunate, because there are clear links between popular understandings of mental illness and whether people in mental distress seek help or feel able to disclose their problems (Littlewood 1998). The core experiences of shame (to oneself or to one's family) and blame (from others) are common, although they vary between cultures. However, international studies have shown that discrimination of people with mental disorders is consistently common across cultures (Thorncroft et al. 2009; Lasalvia et al. 2013).

The stigma concept can be traced back to Goffman (1963) and social interactionists, who focused on the role of social interaction in stigma, including labelling and stereotyping. This view has been challenged by theorists who focus on structural stigma and discrimination; they argue that legislation and empowering people with mental disorders will reduce stigma. Link and Phelan reconciled these different approaches in 2001 in their modified labelling theory (Link and Phelan 2001). They identify stigma as a process involving labelling, stereotyping, separation, status loss, and discrimination. They highlight structural discrimination and disadvantage, and the fact that social, economic, and political power is necessary to stigmatize.

Unfortunately, not even large-scale and expensive anti-stigma campaigns have shown much promise in achieving changes in public attitudes (Sartorius 2010; Henderson and Thorncroft 2013). A combination of positive social contact with people with mental disorders, protest against stigmatizing messages and measures, and education seems to be most effective in fighting stigma. Social contact has shown to be the most promising evidence-based intervention method, including 'proxy' contact, for example, a narrative through a film (Quinn et al. 2011). It seems to be more productive to focus on promoting positive messages and strengths rather than dispelling negative beliefs. Programmes should offer a chance to revise stereotypes through identification with ordinary people and peers. Positive models of extraordinary people with mental disorders may not have the intended effect, because they can be dismissed as exceptions to the

norm. At best, anti-stigma activities providing social contacts are mainstreamed in school curricula and training of professionals. Awareness of mental health among young Europeans in combination with role-play activities stimulating social interactions in the classroom and increasing understanding that mental health problems can be prevented are well perceived and attractive to young people (Wasserman et al. 2012).

Sensational reporting and reporting with negative undertone about mental health problems is common in the media. Many national campaigns have a network of contacts who protest against negative stories on the radio, newspapers, or television by using letters, email, and the telephone. This may be effective against reporting that people with severe mental illness are dangerous. Public protests have played a limited role in mental health campaigns compared to other civil rights movements, perhaps due to the very deeply held prejudice in society and potential for ridicule (Goldie et al. 2012).

Mental health determinants

Social, behavioural, and biological sciences have provided substantial insight into the role of risk and protective factors in the developmental pathways to mental health and mental disorders. Biological, psychological, social, and societal risk and protective factors and their interactions have been identified across the lifespan from as early as fetal life. Many of these factors are amendable and, therefore, potential targets for promotion and prevention measures. Other socioeconomic and environmental determinants for mental health problems and disorders are related to macro-issues such as poverty, lack of freedom, war, and inequity (WHO 2004).

The roots of mental health and mental disorders often lay in early life. It is well documented that poor nutrition, exposure to toxic substances such as alcohol during pregnancy, trauma during labour, maternal depression, parental neglect, sexual abuse, other forms of trauma, and lack of stimulation can impact a child's cognitive development and socioemotional status (Richter et al. 2010).

Mental health and mental illnesses are determined by multiple and interacting social, psychological, and biological factors. Individual, familial, and societal determinants of mental health often lie in non-health domains such as social policy, education, and urban planning. Promising evidence has, however, indicated that effective interventions exist (Doughty 2005): interventions in local communities (Hawkins et al. 2002), child support programmes, home visiting programmes (Olds 2002), and school programmes (Weare and Nind 2011) are some examples of effective interventions for improving mental health.

Research has, so far, mainly focused on determinants of mental ill health, largely neglecting the need to identify both risk and protective factors. Lately, there has been a heightened interest in the determinants of positive mental health and well-being. Evidence indicates that social relationships are critical for promoting well-being and buffering against mental ill health (Diener and Seligman 2002). This seems to be the case for people across all ages (Forsman et al. 2013). Although food choices are often linked to well-being in popular press, the evidence on the role of different nutritional factors is complex; thus, the direct links between eating well and feeling good remain ambiguous until more research is completed (Kirkwood et al. 2008). Not enough is known about the

effects of physical exercise on mental health. Longitudinal studies provide some evidence to indicate that physical activity protects against cognitive decline in later life and the onset of depressive symptoms and anxiety (Kirkwood et al. 2008).

Mental disorders are, in the developed and developing world alike, associated with disadvantage. Many vulnerable groups are more affected by mental health problems and die more often from suicide. The greater vulnerability of disadvantaged people to mental illnesses may be explained by such factors as the experience of insecurity and hopelessness, rapid social change, and the risks of violence and physical ill health.

Major individual socioeconomic risk factors for mental health problems and suicide are poverty, poor education, unemployment, high debt, social isolation, and major life events. Socially excluded and deprived people are at a higher risk of developing mental health problems, especially depression.

On the community level, suicides are linked with socioeconomic deprivation and unemployment (Rehkopf and Buka 2005; Middleton et al. 2006). In Europe, between 1970 and 2007, a more than 3 per cent increase in national unemployment rate was linked to a 4.5 per cent increase in suicides (Stuckler et al. 2009). Suicides are also linked to social isolation, physical illness, substance abuse, family violence, and access to lethal means of suicide.

The effects of work on mental health are complex. On the one hand, work is a source of personal satisfaction and accomplishment, interpersonal contacts, and financial security. These are all prerequisites for good mental health. The workplace social capital (i.e. trusting relationships) has been shown to protect against depression (Oksanen et al. 2010). Those who become unemployed are twice as likely to have increased depressive symptoms and to be diagnosed with clinical depression compared to those who remain employed (Dooley et al. 1994). On the other hand, there is evidence indicating that a high workload, precarious work, and high emotional demand, as well as school or workplace bullying and violence, are linked with depression.

Prenatal maternal stress is a risk factor for behavioural and mental disorders, including depression. Those born small, due to fetal stressors, have an increased risk of mental disorders (Wahlbeck et al. 2001; Räikkönen et al. 2008; Lahti et al. 2010), as well as of suicide completion and attempt (Mittendorfer-Rutz et al. 2004). Hostile, unstable, and unsupportive parent-child relationships can lead to depression later in life. Corporal punishment, harsh parenting and child abuse (physical, sexual, and emotional), temporary separation (Räikkönen et al. 2011) from parents, and inter-parental conflict are associated with adverse psychological outcomes (Sarchiapone et al. 2007) and disorders in childhood (Madigan et al. 2007) and adolescence (Allen et al. 2007). Children of parents with depression are a high-risk group: six in ten will develop a mental disorder before the age of 25 (Beardslee et al. 1993). Promoting a nurturing early interaction between caregivers and the child increases resilience in the face of adverse life events and promotes life-long mental health and well-being.

Substance use is a risk factor for mental disorders. Alcohol use, for instance, causes depression (Rehm et al. 2003). Alcohol problems lead to a more serious course of depression, including earlier onset of the disorder, more episodes of depression, and more suicide attempts (Sher et al. 2008). A rise in per capita alcohol consumption has been linked to a post-war rise in suicide mortality in many European countries (e.g. Denmark, France, Hungary,

Norway, and Sweden), but not in southern Europe (Norström and Ramstedt 2005). The link seems to be more pronounced in countries where strong spirits dominate the consumption. There is strong evidence supporting the effectiveness of policies that regulate the alcohol market, for example, by taxation and restricting access, in reducing the harm done by alcohol (Anderson 2006). A natural experiment in the former USSR during the Gorbachev rule in the second half of the 1980s, characterized not only by political reforms, but also by strict limits on the sale of alcohol and restrictive attitude towards alcohol consumption, resulted in history's most effective suicide prevention programme for men (Wasserman et al. 1998). Promotion of a healthy lifestyle and avoidance of harmful drinking are cornerstones in promoting good mental health and preventing suicides.

Mental, social, and behavioural health problems interact, which may intensify their effects on behaviour and well-being. Substance abuse, violence, and abuses of women and children, on the one hand, and health problems such as heart disease, depression, and anxiety on the other, are more prevalent and more difficult to cope with in conditions of high unemployment, low income, limited education, stressful work conditions, gender discrimination, unhealthy lifestyle, and human rights violations.

Well-being and mental health promotion

In recent years, there has been a discernible shift of focus in the field of public mental health from illness to well-being. The emergence of positive psychology, and the science of well-being, has brought with it a greater interest in establishing the underlying causes of positive mental health and well-being. Standardized measures of well-being have been used in population-based surveys (Bech et al. 2003; Tennant et al. 2007) and there are several countries in Northwestern Europe (e.g. England, Iceland, and Scotland) that perform repeated measures of mental well-being in the population.

Mental health promotion aims to improve mental health of the population by strengthening well-being. It implies the creation of individual, social, and environmental conditions that are empowering and enable optimal health and development. Such initiatives involve individuals in the process of achieving positive mental health, well-being, and quality of life. Mental health promotion is an enabling process, done by, with, and for the people.

Common principles and recommendations for modern mental health promotion were laid by The Melbourne Charter in 2008. The Charter provides a framework which recognizes the influence of social and economic determinants on mental health and mental illness, and it identifies the contribution that diverse sectors (including but not exclusive to health) make in influencing those conditions that create or ameliorate positive mental health. The Charter stresses that mental health promotion is everybody's concern and responsibility; that mental well-being is best achieved in equitable, just, and non-violent societies; and that mental health is best promoted through respectful, participatory means where culture and cultural heritage and diversity are acknowledged and valued (Global Consortium for the Advancement of Promotion and Prevention in Mental Health 2009).

In many aspects, the promotion of mental health overlaps with prevention, yet both are distinct. The emphasis in mental health promotion is on positive mental health and well-being (what

can be done to keep people healthy or to become even healthier), rather than illness prevention (what can be done to avoid illness).

Population-based approaches for promoting mental health and well-being utilize principles of public participation, engagement, and empowerment and are implemented in everyday contexts such as in families, schools, and workplaces. Effective mental health promotion builds on cross-sectoral collaboration with non-health sectors, including education, housing, employment and industry, transport, arts, sports, urban planning, and justice.

Disadvantaged and vulnerable populations have a significant need for mental health promotion action. Strengthening mental health adds to the human capital asset of vulnerable populations. The promotion of mental health can play an important role in breaking the intergenerational cycle of poverty and mental ill health through promoting positive mental health outcomes (Petersen et al. 2010).

The concept of well-being comprises two main elements: feeling good (hedonic well-being) and functioning well (eudaimonic well-being). Happiness and enjoyment are aspects of hedonic well-being. Resilience (the capacity to cope with adversity), sense of mastery of one's life, and sense of coherence and optimism are characteristics of eudaimonic well-being (Huppert 2008).

Being in a state known as mindfulness, 'the state of being attentive to and aware of what is taking place in the present', has also been shown to predict positive mental states, self-regulated behaviour, and heightened self-knowledge (Brown and Ryan 2003). Self-determination theory suggests that an open awareness is particularly valuable for choosing behaviours that are consistent with one's needs, values, and interests (Ryan and Deci 2000). This self-regulatory behaviour is thought to be important for well-being.

Although the intervention research-base in mental health promotion is still developing, several effective population-level interventions have been identified (Mrazek and Haggerty 1994). A large range of multifaceted outcomes from mental health promotion programmes have impacted other sectors such as education, labour and employment, and family cohesion; however, effects have often been seen after a longer follow-up time than that usually used in most standard intervention studies.

An important target for mental health promotion interventions is parenting, including early parent-child interaction and approaches to discipline in child upbringing. Programmes should address the intergenerational transition of poor parenting; abused and neglected children are more likely to become adults who are hostile, reject parenting, and display negative discipline practices towards their own children. Parenting support practices need to focus on the positive, taking an empowering approach, and enhancing positive mother-infant and father-infant interaction and enjoyment (Stewart-Brown et al. 2011).

Promoting a nurturing early interaction between caregivers and the child increases the resilience of children in the face of adverse life events and promotes life-long mental health and well-being. Home visitation programmes that provide counselling, as well as a specific intervention to strengthen parent-child interaction, have been shown to be effective when delivered by trained lay women in developing countries (Cooper et al. 2009), and by trained nurses in developed settings (Olds 2002). Such programmes have shown good effects, improving maternal sensitivity and reducing intrusiveness and improving attachment of children (Cooper et al. 2009).

The past two decades have seen a significant growth of research and good practice on mental health prevention and promotion in schools. Schools are an important setting for mental health promotion, through their role in helping to establish identity, interpersonal relationships, and other transferable skills. Across the world, an increasing number of schools are engaging in a wide range of mental health-related initiatives and policies, which, in many places, are showing promising results. Activities operate under a variety of headings, not only 'mental health', but also 'social and emotional learning', 'emotional literacy', 'emotional intelligence', 'resilience', 'life skills', and 'character education'. There is growing evidence showing the effectiveness of mental health promotion in schools. Positive impacts include the reduction of depression, aggression, impulsiveness, and antisocial behaviour, as well as the development of proficiencies that promote mental health such as cooperation, resilience, a sense of optimism, empathy, and a positive and realistic self-concept. Programmes have also been shown to help prevent and reduce early sexual experience, alcohol and drug use, violence and bullying in and outside schools, to promote pro-social behaviour and, in some cases, reduce juvenile crime (Weare and Nind 2011). Furthermore, mental health promotion programmes significantly improve academic performance. A meta-analysis summarized research on 213 social and emotional learning programmes and found that schools with effective programmes had an 11 percentile improvement in achievement tests, a 25 percentile improvement in social and emotional skills, and a 10 percentile decrease in classroom misbehaviour, anxiety and depression. Data indicates that successful school programmes include those with a sequential and integrated skills curriculum, active forms of learning to promote skills, and a focus on skill development and explicit learning goals (Durlak et al. 2011). Teacher well-being is an important component of the whole-school approach to mental well-being; results of an European study (Wasserman et al. 2010; Carli et al. 2013) showed that psychological well-being of teachers is linked to teachers' readiness to help pupils with mental health problems (Sisask et al. 2014).

For the adult population, the workplace is an important setting for mental health promotion. Actions can be implemented at both an organizational level within the workplace and targeted at specific individuals. The former can target managers and include measures to promote awareness of mental health and well-being in the workplace and improve managers' skills in risk-management of stress and poor mental health. This can be achieved by examining job content, working conditions, terms of employment, social relations at work, modifications to the physical working environment, flexible working hours, improved employer-employee communication, and opportunities for career progression. Actions targeted at individuals can include modifying workloads, providing cognitive behavioural therapy, relaxation and meditation training, time management training, exercise programmes, journaling, biofeedback and goal-setting. Structuring employment to create 'good work' brings health benefits to the individual, financial benefits to the corporation, and both direct and indirect improvements to the fabric of society. Effective programmes address work context, work content, and individual resilience. Effective management styles are those that promote organizational justice, workplace support, control possibilities of the work demand, active participation of employees,

and provide clear and consistent communication. Effective work content is that which protects employees from unreasonable job demands, promotes employee control and autonomy, flexible working schedules, and job stability. For individuals, effective comprehensive programmes are those that promote training in both resilience and stress management (Czabała et al. 2011).

For older people, the most promising interventions promoting mental health include social activities. Studies have shown that associations exist between social capital in the ageing population and mental health (Forsman et al. 2011b, 2012). Crucial components of the individual-level social capital concept, such as social support and social network size, are negatively associated with depressive symptoms and depression, while loneliness is linked to depressive symptoms and depression. Research has highlighted that civic mistrust and lack of reciprocity or social participation (i.e. low individual-level social capital) are associated with depressive symptoms among older adults. Mental health of older adults can be strengthened by addressing social capital. With an increasing retirement age in many countries, work may well have a protective effect for older people, but only if it is flexible enough to take into account older people's differing capabilities and needs. Data highlight the effectiveness and subjective importance of social activities in maintaining mental health and well-being among older adults. The social activities are an important mental health resource among older adults, because of the accompanied sense of belonging to a social group, as well as feelings of purpose, with regard to everyday life and hope for the future. Psychosocial interventions aiming to increase the social contacts of older participants tend to improve mental well-being, as this reduces feelings of loneliness. In a recent systematic review and meta-analysis, social activities among older people significantly reduced depressive symptoms when compared to no-intervention controls (Forsman et al. 2011a).

Prevention of mental disorders

Prevention of mental health problems and disorders has a long history. The early ideas of the mental hygiene movement, at the beginning of the twentieth century, were first translated into experimental activities in primary healthcare, schools, and public health practices. However, the systematic development of science-based prevention programmes and controlled studies to test the effectiveness of preventive interventions did not emerge until around 1980. Since then, the multidisciplinary field of prevention science in mental health has developed at a rapid pace, facilitated by increasing knowledge on malleable risk and protective factors, generating evidence showing that preventive interventions can influence risk and protective factors and reduce the incidence and prevalence of some mental disorders (WHO 2004).

Mental disorder prevention aims at reducing occurrence, frequency and relapses, the time spent with symptoms, or the risk for a mental illness, preventing or delaying their occurrence and decreasing their impact in the affected person, their families, and society. Recently, there has been a wider acceptance and recognition of the importance of prevention in mental disorders.

Many of the effective preventive measures are harmonious with principles of social equity, equal opportunity, and care of vulnerable groups in society. Examples of these interventions include improving nutrition, ensuring primary education, access to the

labour market, removing discrimination based on race and gender, and ensuring basic economic security. A particularly potent and unfortunately common threat to mental health is conflict and violence, both between individuals and between communities and countries. The resulting mental distress and disorders are substantial. Preventing violence requires larger societal efforts, but mental health professionals may be able to ameliorate the negative impact of these phenomena by implementing some specific preventive efforts and making humanitarian assistance more mental health friendly (WHO 2004).

Prevention can be categorized in a number of ways: primary prevention focuses on addressing wider determinants across whole populations. Depending on the target group, primary prevention can be universal, selective, or indicated. Selective prevention focuses on targeting groups at higher risk of developing a disorder. Indicated prevention targets high-risk people who are identified as having minimal, but detectable, signs or symptoms foreshadowing mental disorder or biological markers indicating predisposition for mental disorder, but who do not meet all diagnostic criteria for a disorder at that time. Secondary prevention involves early detection and intervention. Tertiary prevention involves working with those with an established disease in order to promote recovery and reduce the risk of relapse (Mrazek and Haggerty 1994; Campion et al. 2012).

It is increasingly accepted that prevention efforts will have a broader spectrum impact, not only on mental health, but also on employability, educational achievement, and social adjustment. This is due to common risk factors for mental disorders and possibilities in life. By acting on common risk factors, instead of trying to prevent specific disorders, a range of positive outcomes will be achieved.

The postnatal period is important for the mental health in mother and child. Research shows that the mother's depression has consequences on the cognitive development of the baby. It has been repeatedly shown that children of families with parental mental disorder have an increased risk of developing mental disorders. A range of interventions have been developed aiming to prevent trans-generational transfer by addressing risk and protective factors in children and their families. Issues addressed include the family's knowledge about mental illness, fostering psychosocial resilience in children, improving parent-child and family interactions, diminishing stigma, and increasing social network support. Some interventions target early parent-child interaction; others use a whole-family approach during childhood and early adolescence or focus on the children at risk themselves. A recent systematic review and meta-analysis indicated that the risk of mental disorders in the offspring can be reduced by 40 per cent by preventive interventions (Siegenthaler et al. 2012).

There is strong evidence showing that improving nutrition and development in socioeconomically disadvantaged children can lead to healthy cognitive development, improved educational outcomes, and reduced risk for mental ill health, especially for those at risk or who are living in impoverished communities. The most effective intervention models combine nutritional interventions (such as food supplementation) and growth charts with counselling and psychosocial care (e.g. warmth, attentive listening) (WHO 2004). In addition, iodine, which secures an adequate function of the thyroid, plays a key role in preventing mental and physical retardation and impairment in learning ability. A low to

moderate iodine intake during early gestation has been linked to lower verbal IQ and poorer reading ability of offspring at age 8–9 years. Iodine supplementation programmes ensure that children obtain adequate levels of iodine through iodized salt or water. Pregnant women may in addition need targeted prevention actions to ensure sufficient iodine intake (Bath et al. 2013).

Bullying among youth is a significant public health problem; it is prevalent and frequently has detrimental effects. Being a victim of bullying is associated with being depressed or anxious, poor social and emotional adjustment, and lower academic achievement (Hertz et al. 2013). Data indicates a causal association between being a bully-victim and subsequent depression and panic disorder as well as subsequent suicide-related behaviours (Klomek et al. 2010; Copeland et al. 2013). Prevention of bullying would improve mental health outcomes for many young people, and effective anti-bullying prevention programmes have been developed. A meta-analysis of school bullying strategies concluded that whole-school approaches that included multiple disciplines and complementary components directed at different levels of school organization more often reduced victimization and bullying than the interventions that only included classroom-level curricula or social skills groups (Vreeman and Carroll 2007).

Community systems-strengthening has its roots in the action that communities have always taken to protect and support their members. Modern approaches to community healthcare are reflected in the WHO Alma Ata declaration of 1978, and in more recent WHO work on the social determinants of health (WHO n.d.). Community systems-strengthening interventions focus on developing empowering processes and building a sense of ownership and social responsibility within community members. An example of such an intervention is the *Communities that Care* (CTC) programme, which has been implemented successfully in the United States and is currently being adopted and replicated in several developed countries. The CTC intervention activates communities to implement community violence and aggression prevention systems (Hawkins et al. 2002). The strategy helps communities use local data on risk and protective factors to identify risks and develop actions. These include interventions that operate simultaneously at multiple ecological levels: the community (e.g. mobilization, media, and policy change), the school (e.g. changing school management structures, curricula, and teaching practices), the family (e.g. parent training strategies), and the individual (e.g. social competence strategies). Evaluations at various CTC sites have indicated improvements in youth outcomes such as reduction in school problems, weapons charges, burglary, drug offences, and assault charges.

There is rich evidence showing that conduct disorders, aggression, and violence of young people can be prevented. The most successful preventive interventions to reduce the risk of aggressive behaviour and conduct disorders focus on improving the social competence and pro-social behaviour of children, parents, peers, and teachers. Universal interventions that have been shown to have a successful impact on conduct problems are all school based and include classroom behaviour management, enhancing child social skills, and multimodal strategies, including the involvement of parents. Classroom behaviour management programmes (e.g. *Good Behaviour Game*) attempt to help children better meet the social demands of the classroom through the

overt encouragement of desired behaviours, and the discouragement of undesired behaviours. Social skills programmes (e.g. *I Can Problem Solve* or *Promoting Alternative Thinking Strategies* (PATHS)) attempt to provide children with cognitive skills that may help them cope better with difficult social situations. Skills related to listening, empathy, interpersonal problem-solving, and conflict and anger management are taught in a classroom setting. Also, selective interventions designed for a variety of settings have been found to be effective in preventing conduct problems, including prenatal and/or early childhood programmes and school or community-based programmes. Prenatal and/or early childhood programmes usually attempt to improve the skills of parents to nurture, support, and teach their children pro-social behaviour patterns and/or to develop the social skills of children. These programmes have been shown to decrease child conduct problems during adolescence, including reductions in violence and police arrests. School- or community-based programmes for selective child populations at risk have successfully targeted child social and problem-solving skills and/or parent management skills, resulting in a decrease in negative parent–child interactions and teacher ratings of conduct problems at school (Powell et al. 2007).

Recent research demonstrates that depressive episodes can be prevented in a cost-effective way and even in a cost-saving way (Cuijpers et al. 2012). Preventive interventions can reduce the incidence of new episodes of MDD by about 25 per cent. Adding a stepped-care model to the preventive intervention may reduce the number of new episodes even more (van't Veer-Tazelaar et al. 2009). Methods with proven effectiveness involve educational, psychotherapeutic, pharmacological, lifestyle, and nutritional interventions. School-based programmes targeting cognitive, problem-solving, and social skills of children and adolescents (e.g. *The Resourceful Adolescent Programme*) have reported a reduction in high depressive symptom levels of 50 per cent or more a year after the intervention. Several selective interventions targeted at coping with major life events have shown significant and long-term reduction in high levels of depressive symptoms, such as programmes for children with parental death or divorce or for unemployed adults. Indicated programmes for those with elevated levels of depressive symptoms, but no depressive disorder, have shown significant effects in reducing high levels of depressive symptoms and preventing depressive episodes. Such programmes mainly use a group format to educate people at risk in positive thinking, challenge negative thinking styles and improve problem-solving skills and have been shown to be effective in school (Clarke et al. 1995) or primary care settings.

Anxiety disorders can successfully be prevented by strengthening emotional resilience, self-confidence, and cognitive problem-solving skills in school-aged children. Cognitive behavioural programmes (e.g. the *FRIENDS* programme) have significantly reduced the first onset of anxiety disorders in school children (WHO 2004).

The evidence for the effectiveness of interventions in preventing post-traumatic stress disorder (PTSD) is limited. However, some studies show that PTSD severity can be reduced by brief preventive trauma-focused cognitive behavioural therapy (CBT). Psychological debriefing does not reduce the incidence or severity of PTSD or related psychological symptoms in civilian victims of crime, assault, or accidental trauma and should not be routinely offered (Gartlehner et al. 2013).

Several eating disorder prevention programmes have been developed and tried among children and adolescents. There is currently limited evidence in the published literature to suggest that any particular type of programme is effective in preventing eating disorders. Eating disorder prevention programmes, based on challenging the thin ideal (*The Body Project*) or promoting energy balance (the *Healthy Weight* intervention) have reduced the risk of future onset of eating disorders, but more research on their effectiveness is needed before large-scale implementation of eating disorder prevention programmes can be initiated (Stice et al. 2013).

Substance abuse disorders can be prevented by universal policy actions by reducing the availability of alcohol and drugs. Effective regulatory interventions include taxation, restrictions on availability, and total bans on all forms of direct and indirect advertising. Policy interventions aimed at reducing the harm from addictive substances have led to the prevention of substance use disorders. When applied to alcohol, education and persuasion strategies usually deal with less alcohol consumption, the hazards of driving under the influence of alcohol, and related topics. Despite their good intentions, public service announcements are considered an ineffective antidote to the high-quality pro-drinking messages that appear much more frequently through paid advertisements in the mass media.

Psychoses are severe mental disorders with a peak incidence in late adolescence and early adulthood. Universal and selective interventions are not yet viable strategies in the prevention of psychoses. The indicated prevention approach and early identification and intervention present promising possibilities to reduce the burden of schizophrenia and other psychoses. Typically, there is a delay of 1–2 years between the onset of schizophrenia and initiation of treatment, due to failure in identifying psychosis, which, in many cases, may have a slow and gradual onset. A prolonged duration of untreated psychosis has been linked to worse outcome. Several population-based preventive programmes have been developed to reduce the duration of untreated psychosis. Improving community awareness and mental health literacy of the general population reduced the delays into treatment in the Norwegian *Treatment and Identification of Psychosis Study* (TIPS) and subsequent studies in Australia. Results in the prevention and delay of transition to psychotic disorder from high-risk state, mostly involving second-generation antipsychotics and CBT, are promising, but currently still insufficient to make recommendations or to be translated into public health practice (Correll et al. 2010).

Prevention of suicides

Public health approaches to suicide prevention have to integrate societal and cultural viewpoints with medical and psychological viewpoints to develop strategies that will save most lives in an effective and measurable way.

Suicides can be prevented by public health actions and suicide prevention has consistently been shown to be highly cost-effective. Considerable evidence is available for the effectiveness of broadly applied population-level interventions, such as restriction of access to lethal means of suicide, responsible media coverage of suicide issues, and community-based multilevel interventions targeting primary care providers, gatekeepers, general populations, and patients with their relatives. The evidence for targeted

interventions, which address high-risk groups, such as people who self-harm, people bereaved by suicide, and people with severe mental illness is less convincing but promising (Wasserman et al. 2012). However, selective prevention focusing on high-risk groups is important from the ethical point of view, as it diminishes suffering for the individuals and their families. Although suicide rates are higher in the high-risk groups than in the general population, universal approaches hold the potential to prevent a greater number of deaths (Pitman and Caine 2012).

Preventing suicide by restricting access to lethal methods of suicide is effective. The restriction of access to common and highly lethal suicide means, such as toxic substances and firearms, is successful in reducing suicides. Restriction of one suicide mean seems not to lead to a switch to another. The probability of individuals attempting suicide decreases when they are precluded from implementing a preferred method. Although some individuals might seek other methods, many do not; when they do, the means chosen are less lethal and are associated with fewer deaths than when more dangerous ones are available. When a lethal method is unavailable at the moment of potential action, suicide attempts might be delayed so that, in some cases, suicidal impulses will pass without fatal effects (Yip et al. 2012).

As a public health measure, means restriction has a long history; removal of the pump handle in Broad Street, London, United Kingdom, by John Snow in 1854 was an early example and a historic landmark in public health practice (Johnson 2006). Means restriction entails a community or societal action that does not depend on an individual's intention or volition. Applied to the population as a whole, it typically affects people whose suicide risk is otherwise undetected, and who do not seek therapeutic assistance to prevent their crisis or for life-saving interventions when necessary. Removal or restriction of access to a lethal method changes the context of a potential suicide by precluding potentially fatal actions or forcing the use of a less lethal method.

Application of universal measures for means restriction might be considered intrusive by the general public. The resistance to restrictions and safety measures is underpinned by the common misperception that, despite data showing powerful population level effects, a seriously suicidal person will inevitably find a way to die and that all methods have roughly equal case fatalities. In order to implement means restriction, it is important to address these misunderstandings and gain community support.

Choice of suicide mean varies according to the country and even inside one country, and by age and gender (Ajdacic-Gross et al. 2008). Suicide means used also vary over time. These patterns suggest a close link to differences in the availability and lethality of specific suicide means. Due to availability of pesticides, suicides by pesticide poisoning are common in agrarian populations in Asia (Phillips and Gunnell 2009), whereas access to high buildings and bridges make jumping from high places a common mean of suicide in urban settings (Beautrais and Gibb 2009; Chen and Yip 2009).

In times of peace, most firearm-related deaths are suicides. Enforcement of gun-control policies (e.g. purchase restrictions, waiting times for gun purchase, higher age limits, licensing of firearm owners, safe storage precautions) lowers numbers of firearm suicides (WHO 2010). Empirical data suggest that firearm regulations, which function to reduce overall gun availability, have a significant deterrent effect on male suicide, while regulations that seek

to prohibit high-risk individuals from owning firearms have a lesser effect (Rodriguez Andrés and Hempstead 2011). Having a firearm in the home increases the risk of a violent death in the home; the risk of dying from a suicide in the home was tenfold greater for males in homes with guns than for males without guns in the home. Persons with guns in the home were 30-fold more likely to have died from suicide committed with a firearm than from one committed by using a different method (Dahlberg et al. 2004). Guns are highly lethal, require little preparation, and may be chosen over less lethal methods to commit suicide, particularly when the suicide is impulsive. Removal of firearms from people's homes by regulatory means is desirable and would result in a reduction of suicides, but may be difficult to achieve in countries with a strong pro-gun lobby.

Safe environments (e.g. safety doors on railway platforms, barriers on bridges, locked storage of firearms) contribute to suicide prevention. Prevention of suicide can be taken into account during the planning process or after an environment (e.g. bridges and railways) has been identified as a suicide hot-spot (Beautrais et al. 2009; Ladwig et al. 2009).

Improving the awareness and coping skills of the general public, gatekeepers (such as youth workers, police officers, and teachers), general practitioners (GPs), and other healthcare professionals to identify people at risk of suicide has been shown to be an effective way to prevent suicide (Hegerl et al. 2009; Hoven et al. 2009). Responsiveness of services to the needs of individuals with suicidal behaviours is an essential component of suicide prevention. Training of GPs and other healthcare staff to identify depression and substance use problems, and provide adequate treatment has been successful in reducing suicidality and suicides (Appleby et al. 2000). This method is especially useful for preventing suicides in females, as in a number of cultures females have a greater tendency than males to seek help from healthcare professionals (Hadlaczky and Wasserman 2009).

There is significant evidence from around the world to indicate that highly sensationalized reporting of suicides,

providing detailed descriptions of the method used, can and does lead to 'copycat' suicides. Suicide contagion is a concept from the infective disease model and assumes that suicidal behaviour may facilitate the occurrence of subsequent, similar behaviours. Imitation refers to the process that explains the occurrence of contagion. Suicide contagion has been investigated primarily in adolescent populations, revealing that up to 5 per cent of all adolescent suicides may be the result of suicide clustering (Westerlund et al. 2009). On the other hand, responsible reporting on suicides reduces copycat suicide, especially among adolescents (Niederkrotenthaler and Sonneck 2007). Liaising with media as well as using the Internet-based systems has an important role in educating the public about depression, suicide preventive methods and responsible coverage of suicide (Westerlund and Wasserman 2009). Media guidelines for reporting suicides and monitoring of stigmatizing media reports have been linked with reduced stigmatization in the press and reduction of suicides. Such reporting guidelines can be based on recommendations set forth by the WHO (2000).

Mental health services

Design, management, and evaluation of mental health services are a core task of public mental health. Today, mental health service provision is in a global transition from hospital-based systems to community-based systems. The change reflects the growing evidence of what constitutes cost-effective care; it also acknowledges the failures concerning issues of social inclusion and human rights of the care systems, which were based on the old-fashioned and remote institutions (asylums).

The recent history of mental health services can be seen in terms of three periods: first, the rise of the asylum; second, the decline of the asylum; and third, balancing mental health services (Table 8.7.1).

Table 8.7.1 The key characteristics of the three periods in the historical development of mental health systems of care

Period 1: the rise of the asylum	Period 2: the decline of the asylum	Period 3: balancing mental services
Asylums built	Asylums neglected	Asylums replaced by smaller facilities
Increasing number of hospital beds	Decreasing number of hospital beds	Decrease in the number of beds slows down
Reduced role for the family	Increasing but not fully recognized role of the family	Importance of families increasingly recognized, in terms of care given, therapeutic potential, the burden carried, and as a political lobbying group
Public investment in institutions	Public disinvestment in mental health services	Increasing private investment in treatment and care and focus in public sector on cost-effectiveness and cost containment
Staff: doctors and nurses only	Clinical psychologist, occupational therapist, and social worker disciplines evolve	More community-based staff and emphasis on multidisciplinary team working
	Effective treatments emerge, beginning of treatment evaluation and of standardized diagnostic systems, growing influence of individual and group psychotherapy	Emergence of 'evidence-based' psychiatry in relation to pharmacological, social, and psychological treatments
Primacy of containment over treatment	Focus on pharmacological control and social rehabilitation, less disabled patients discharged from asylums	Emergence of concern about balance between control of patients and their independence

A modern mental healthcare system is based on balanced care, that is, it includes both modern community-based and modern hospital-based care. In balanced care, the focus is on services that are provided in normal community settings, as close to the population served as possible, and to which admissions to psychiatric wards in a general hospital can be arranged promptly, but only when necessary (Thornicroft and Tansella 1999, 2002; Gaebel et al. 2012).

A health policy supporting the integration of health and social services, and the mainstreaming of mental health services into primary care, improves access to care. Integrating mental health services into general healthcare is the most viable way of implementing balanced care, closing the treatment gap and ensuring that people get the care they need. Because of the high prevalence of mental disorders, only complex and/or severe cases should be treated by specialized mental healthcare. To achieve this consistently, the services need to identify priority groups who should receive access to specialist care from among the 25 per cent of the whole population who suffer from a mental disorder in any given year. Well targeted services are those in which specialist care concentrates on providing direct services to people with the most severe degree of symptoms and disability. Primary care responsibility for common mental health disorders should be supported by accessible referral systems and specialist supervision (Tansella and Thornicroft 1999). Providing even minimal psychotherapy in primary care can prevent full-blown depression (Smit et al. 2006). Programmes aimed at education of primary care physicians have improved the detection of depression and even led to a decrease in suicides due to depression (Rutz 2001). The use of new media, such as e-mental health and smart phone technologies, and the use of lay health counsellors, may boost dissemination of mental health interventions, especially in low- and middle-income countries.

Another cornerstone of a balanced care system is the provision of safe and high-quality home and community-based specialist services. Any developed mental healthcare system encompasses specialized community services for children and adolescents. A modern mental health system includes crisis resolution teams, home treatment, assertive outreach and early intervention teams, day treatment facilities, and supported work. Collated evidence suggests that supported employment schemes, which consist of arranging early placement in normal work with variable support from staff, may offer better outcomes than sheltered or transitional employment approaches. People suffering from mental disorders who want to work should be offered the option of supported employment as part of their treatment package. Current evidence indicates that supported work improves clinical outcomes and supports social inclusion of people with severe mental disorders (Crowther et al. 2001).

In diversified modern mental healthcare systems, particular attention needs to be paid to maintaining high-quality communication between all parts of the care system. There is a need to address three types of interfaces: (1) those within the mental health service, between its components; (2) those within the health service, between mental health and other services (both primary and secondary care); and (3) those between health and other public services, including social services and housing departments.

Available evidence indicates that community-based and diversified mental health systems, with a wide range of services, are superior to hospital-centred mental health systems,

according to a range of outcomes. For instance, community-based, well-developed and multifaceted mental health services have been linked with lower suicide rates than hospital-based traditional services (Pirkola et al. 2009). Discharged patients benefit from well-developed community care; community follow-up within 7 days of psychiatric discharge has shown a significant reduction in suicides among recently discharged psychiatric patients (While et al. 2012).

A core element of modern mental healthcare is the empowerment of service users and informal carers. Historically, people with mental health problems have lacked a voice. Empowerment translates into being treated with dignity and respect in mental health services and participation of users and carers in decisions. Data suggest that the possibility to exercise control and influence leads to positive mental health outcomes. These outcomes include increased emotional well-being, independence, motivation to participate, and more effective coping strategies. Key issues that users and carers have expressed to be important to advocate for are the rights to autonomy and self-determination, to acceptable and accessible services, user-led evaluation of services, the right for everyone to be recognized as a person before the law without discrimination, the de-stigmatization of mental disorders, and more inclusive and respectful services with user and carer involvement (WHO 2005). Increased use of peer support and 'experts by experience' in the provision of mental health services will support empowerment of service users and improve services.

Development of mental health service systems requires access to reliable data on mental health services and trends in mental health service provisions. International benchmarking, based on comparable data, is an important moving force for the development of mental health services in countries. Unfortunately, mental health information systems, in most countries, are geared towards hospital data, which are of less interest when developing a community-based mental health service provision system. Many highly relevant aspects of modern service provision, such as patient choice, service user empowerment, and respect for human rights, are hardly ever covered by health information systems (Wahlbeck 2011a).

Dental public health

Peter G. Robinson and Zoe Marshman

Introduction to dental public health

Poor oral health is a major public health problem. The considerable burden of oral disease at a societal level reflects the cumulative impact of many people affected to a modest degree. Oral diseases are exceedingly widespread. Their impact on individuals and the community are significant, ranging from mortality to effects on general health and quality of life, and in terms of direct costs and lost productivity.

Frequency of oral disease

Despite decreases over the last three decades, the prevalence of tooth decay is still staggering. For example, England has among the best child dental health in the developed world, yet 38 per cent of 5-year-olds have clinically significant tooth decay. Worldwide, the mean number of decayed, missing, or filled teeth among 12-year-olds is 1.67. Periodontal diseases are almost as common. More than 80 per cent of adults have inflamed gums (gingivitis) and most have evidence of destruction of the attachment between tooth and bone (periodontitis). Oral cancer is the eighth most common cancer worldwide and its incidence is increasing in some Western European countries. The highest reported incidence rates are in India and Sri Lanka where the mouth is the most common site, comprising up to 40 per cent of all cancers.

All the oral diseases of public health importance follow the same pattern of social inequality as general health conditions. In many developed countries, childhood tooth decay is a disease of poverty. For example, 5-year-olds living in the most deprived areas of England have five times the amount of decay as those living in the least deprived. Similar patterns are evident for periodontal diseases, trauma, and cancer.

Impacts of oral disease

Mortality from oral cancer is related to the site in the mouth and the timing of the diagnosis, but 5-year survival is still less than 50 per cent. In addition to mortality, oral disease affects other aspects of general health. Limited dietary choice and calorific and micro-nutrient intake are direct consequences of conditions such as xerostomia, poorly fitting dentures, and loss of teeth. Early childhood caries limit growth and development at the most important stage of life.

Oral diseases also directly affect quality of life. Dental pain is very common. In the United Kingdom, 29 per cent of dentate adults and 26 per cent of 12-year-olds reported oral pain in the past 12 months (Pitts and Harker 2004; Steele and O'Sullivan 2011). Even the appearance of the mouth is hugely important,

affecting self-esteem and our willingness to interact with others. People with visible dental disease are judged by others to be less socially and intellectually competent and less well psychologically adjusted. Good dental appearance is regarded as a requirement for some prestigious occupations.

Considerable effort has been made to assess the extent to which oral disorders compromise aspects of daily life. This is beginning to reveal the determinants of these impacts. In turn, that information is being used to prioritize resources, to suggest avenues for action, and to evaluate interventions.

The cost of oral disease

Direct costs are incurred from the treatment of oral disease as well as the costs of other conditions caused or exacerbated by oral disease. The direct costs have been placed between 0.2 per cent and 1 per cent of the gross national product in developed countries (van Amerongen et al. 1993). The United Kingdom is at the lower end of this range yet the National Health Service (NHS) in England (population 63 million) budgets approximately £2.5 billion (US\$4 billion) for dentistry. This sum is surprising since only about 50 per cent of the population are registered with an NHS dentist. The cost of treatment provided outside the NHS is not known, but may be an additional £1 billion. In the 15 member states of Europe in 2000, the estimated direct cost was US\$68 billion. In Australia in 2008/2009 (population 21.5 million) the cost was US\$7 billion or US\$326 per person (Richardson and Richardson 2011). The cost of the Western model of dental treatment would exceed total national healthcare expenditure in many developing countries.

Indirect costs might include reduced employment or promotion expectations and opportunities, limitation of academic achievement, and the loss of economic productivity. Annually, over 20 million work days and 51 million school hours are lost in the United States alone due to oral disease and its treatment (Department of Health and Human Services 2000), equivalent to 1.5 hours for each employee annually. In Australia, 1.1 million work days and 600,000 school days are lost yearly (Richardson and Richardson 2011). Low-income families are more likely to lose time from work and school because of dental disease, hence compounding the inequalities that already exist in health, income, and educational attainment.

Prevention

Dental caries and periodontal diseases are almost entirely preventable. Clinically significant dental caries occurs only in the presence of excess dietary sugar. Its incidence is low when free sugar intake is less than 15–20 kg/year, roughly 6–10 per cent of

energy intake (Moynihan and Petersen 2004). The use of fluorides, in drinking water or toothpastes, also reduces dental disease. Likewise, the presence of dental plaque is necessary for destructive periodontal disease. Targets for oral cleanliness have been calculated which appear to be compatible with freedom from periodontal disease throughout life (Burt et al. 1985). Slightly higher levels of plaque might be compatible with acceptably low levels of periodontal disease. The risk factors for oral cancer and oral trauma have also been identified and are readily modifiable at a population level.

The scope of dental public health

Dental public health is the science and art of preventing oral disease, promoting oral health, and improving the quality of life through the organized efforts of society.

Major areas of dental public health activity include:

1. Oral health surveillance.
2. Assessing the evidence on oral health and dental interventions, programmes, and services.
3. Policy and strategy development and implementation.
4. Strategic leadership and collaborative working for health.
5. Oral health improvement.
6. Health and public protection.
7. Developing and monitoring quality dental services.
8. Dental public health intelligence.
9. Academic dental public health.
10. Role within health services.

In some countries the specialty also involves provision of services to special population subgroups.

This chapter reviews the epidemiology, aetiology, and management of the four oral conditions of greatest public health importance: dental caries, periodontal diseases, oral cancer, and orofacial trauma. Approaches to oral health improvement are then outlined using the framework of the Commission on the Social Determinants of Health. Finally, we consider future developments in population oral health.

Oral diseases of public health importance

Dental caries

Dental caries and its sequelae account for 93–98 per cent of the burden of oral disease globally. It is the demineralization of tooth substance by acid metabolites of oral bacteria. In the very early stages the lesion appears as a chalky white spot on the tooth. If the lesion progresses, the surface of the tooth breaks down leading to cavitation. If the caries reaches the underlying dentine, it can spread more readily through the porous and less mineralized tissue towards the pulp. Infection of the pulp may allow the passage of bacteria along the root canals to the alveolar bone.

The direct consequences of this process are destruction of the tooth, pain, and a possible dental abscess. When dentine is exposed by cavitation, there may be transient pain associated with hot or cold drinks or sweet foods. Later, as the pulp becomes inflamed, the discomfort may be spontaneous, exquisitely painful,

and of longer duration. In a dental abscess, pressure to the tooth is transmitted to the infected alveolus and the affected person avoids biting or knocking the tooth.

Four factors are necessary for caries development: dietary sugars, a susceptible tooth surface, the microflora of dental plaque, and adequate time.

The evidence implicating sugars in the aetiology of dental caries is convincing. The dental plaque that forms on the tooth surface comprises mainly bacteria, particularly *Streptococcus mutans*, which metabolize sugars to produce acids. The acids cause demineralization of the tooth structure. With each exposure to sugar, the plaque pH falls sharply and rises slowly back to normal levels over the following hour. Hence, caries incidence is related to the frequency of sugar intake.

At high pH, there is remineralization of the tooth, especially in the presence of fluoride. Saliva plays a crucial protective role against caries by simple dilution, by buffering plaque acid, and by acting as a source of minerals and chemical and immunological plaque inhibitory factors. For these reasons, dental caries is more frequent in the sites less accessible to saliva: in the pits and fissures of posterior teeth and between these teeth, and also in people with restricted salivary flow.

Epidemiology

Caries of the permanent dentition is traditionally measured by the number of decayed missing and filled teeth (the DMFT index). More precise indices record the number of surfaces affected (DMFS) and the status of the deciduous dentition (dmf). The index aggregates both disease and treatment experience, hence it is affected by treatment decisions of dentists and is less valid with increasing age. Since each of the categories is equally weighted, it is insensitive to both the severity of the disease and outcomes of treatment.

Nonetheless, the DMFT index, having been used for 75 years, will continue to be used for some time. However, historical DMF scores are not directly comparable with more recent ones as the diagnostic criterion for caries has changed. Previously, diagnosis was based on tooth cavitation detected using a sharp dental probe. Since 2001 the International Caries Detection and Assessment System (ICDAS) has been used to diagnose caries at much earlier stages before cavitation or progression into dentine. Sharp probes are no longer used, preventing damage to the tooth. If no caries is visible the tooth is now judged as having 'no obvious caries'. The lower detection thresholds reflect the emphasis on prevention. In addition to the assessment of the prevalence of caries, its impact is now routinely measured, most frequently by the use of measures of oral health-related quality of life.

Typically, the pattern has been of high caries levels in developed countries associated with exposure to sugars. In the mid 1970s, levels in many developed countries began to fall dramatically, for example, in the United Kingdom, mean DMFT of 12-year-olds decreased from 4.8 to 0.8 between 1973 and 2003 (Pitts and Harker 2004).

This fall in caries prevalence in developed countries appears to have slowed in the early to mid 1980s in the deciduous dentition. The mean DMFT of 5-year-olds in England and Wales fell from 4.0 to 1.8 between 1973 and 1983, but now appears stable at around 1.6 (Pitts and Harker 2004). Nevertheless, children and adults below the age of 50 years have better oral health than preceding

generations. As these cohorts age, there will be commensurate improvements in adult oral health.

Aggregate national data on caries levels are useful, but mask important trends, particularly inequalities in oral health. When disease prevalence was high, disease was almost universal and inequalities were manifest as differences in the number of teeth affected in an individual. With lower disease prevalence, the distribution is highly skewed with typically 20–25 per cent of the population having moderate or severe caries (more than three teeth affected) and the majority having no obvious caries. This affected minority tends to be those living in the most deprived areas. Furthermore, Locker has found that dental caries has little impact on the lives of children and older adults from high-income environments but a more marked impact on those from low-income environments (Locker et al. 2007). These findings reinforce the importance of measuring both the disease impact and prevalence.

Although data are scarce, there are concerns with the rising caries levels in children in some countries undergoing economic growth and nutritional transition. For example, dental caries is very common and severe in 12-year-old children from several Asian and South American countries, but remains relatively low in most African countries where poor economic growth restricts sugar consumption. Here again, national data may mask local variations, particularly high caries levels in urban areas.

Management of dental caries

Until the nineteenth century, tooth extraction was the only useful treatment for dental caries. Treatment evolved to restorative care in which the infected parts of the tooth are removed and replaced with an inert obdurate filling, for example, dental amalgam. During the latter half of the twentieth century, in developed countries, operative treatment for adults has become increasingly complex and technology-intensive. Badly decayed teeth can now be restored with a range of adhesive tooth-coloured materials that are either formed in the mouth or prepared in laboratories and then fitted. Originally, missing teeth could only be replaced with removable dentures. Now they can be replaced with bridges that adhere to the remaining teeth or with prostheses supported by osseointegrated implants that project out through the gingivae. Alternatives to traditional dental drills have been sought to improve the patient's experience of tooth preparation, including the use of lasers and ozone, although these are still not recommended for mainstream use.

Such treatments might reduce the social impact of dental caries on affected people, but play a very minor role in preventing the disease. Dental services accounted for 3 per cent of the caries reduction in industrialized countries during the 1970s compared to the 65 per cent contribution made by broader socioeconomic factors and fluoride toothpastes (Nadanovsky and Sheiham 1994). However, internationally, the emphasis and resources within dentistry remain focused on downstream approaches to 'cure' patients of their dental diseases, rather than evidence-based strategies to improve the oral health of populations (Baelum 2011).

In developing countries, the necessary infrastructure is often not available for complex treatment of carious teeth. In some areas, atraumatic restorative treatment (ART) is the only sustainable method because the decay is removed with hand instruments and the cavities filled with glass ionomer cements. The instruments are easily portable and treatment can be provided painlessly, at

low cost, without local anaesthesia, electricity, or expensive dental equipment. Non-dentists can be trained in the technique in a matter of weeks using manuals available from the World Health Organization (WHO). The technique is most suitable for exactly the types of cavities found in many developing countries with low caries levels. Systematic reviews have confirmed the effectiveness of the ART approach (Frencken et al. 2012).

Implications of changes in caries prevalence

At the low disease prevalence in the developed world, proportionately more caries affects the accessible occlusal surfaces of the teeth. Fissure sealants can be applied to these surfaces to prevent caries and are cost-effective at low caries levels (Armfield and Spencer 2007). Only simple restorations are needed to treat existing disease at these sites. The disease also progresses more slowly, so allowing deferred operative treatment. Many lesions are detected at an earlier stage so that new dental materials can be used in minimally invasive techniques.

Increasing the intervals between dental examinations is safe and effective for children and adults with low disease incidence (National Institute for Health and Clinical Excellence 2004). There is greater scope to employ dental care professionals (DCPs), other than dentists, who can also deliver effective preventive interventions such as fluoride varnish. However, because of the skewed distribution of dental caries, there remains a minority with high levels of caries to be managed.

There are also a large cohort of people more than 50 years old who have suffered from severe dental caries and cycles of re-restoration. This so-called heavy metal generation (Fig. 8.8.1) will continue to need complex and specialized treatment for decades to come with high expectations of retaining their natural dentition into older age.

Periodontal diseases

Periodontal diseases comprise a range of inflammatory diseases of the periodontium: the attachment between gingivae and tooth. In gingivitis, the attachment remains in a healthy position whereas periodontitis is defined by migration of the epithelium which reduces the amount of periodontal ligament and bone supporting the tooth.

Gingivitis, which is exceedingly common, is an inflammatory response to plaque. Along with redness and swelling, the gums may bleed on gentle provocation such as cleaning the teeth. Pain is uncommon. Systemic involvement including hormonal changes, skin diseases, and medication use may modify these diseases or cause other gingival changes. In periodontitis, the loss of periodontal attachment is manifest by deepening of the pockets between the gingivae and teeth and by recession of the gingivae. In severe cases, the supporting structures are so depleted that the teeth become loose. The disease is rarely painful unless an acute infection complicates a periodontal pocket ('a lateral periodontal abscess') or if the exposed root surfaces are temperature sensitive.

Mild periodontal pocketing is common, being seen in approximately half of UK and 63 per cent of US adults (White et al. 2011; Eke et al. 2012). Severe periodontitis is much less frequent. Lost attachment or pockets of 6 mm or more (thought to be sufficient to threaten tooth survival) are seen in 9 per cent of UK and 25 per cent of US adults. These apparent differences between countries may be in part attributed to different survey methods. For example, the 2009–2010 US National Health and Nutrition

Fig. 8.8.1 The 'heavy metal' cohort

Examination Survey examined only adults over the age of 30 and examined the whole mouth. As loss of periodontal attachment is cumulative over a lifetime, restricting the sample to older adults will substantially overestimate the disease prevalence. The disease is more frequent and severe in countries where tooth cleaning practices are less sophisticated.

Periodontitis is hence a substantial problem. It has been consistently linked with psychological and social consequences on everyday life, which intervention studies indicate is reduced by treatment (Jowett et al. 2009). More severe and untreated disease results in the loss of teeth and the need for additional treatment to replace them.

Another periodontal disease of public health importance is acute necrotizing ulcerative gingivitis (ANUG; Vincent's infection or 'trenchmouth'), which causes necrosis, ulceration, soreness, and bleeding of the gingivae. The ulcerated papillae may have a grey slough and there may be a characteristic foetor. Lymphadenopathy and mild fever are variable findings. In many developed countries, ANUG is a disease of young adults. There are no good incidence data, but anecdotally, it has become less frequent among developed populations in recent years. A variant of the disease is associated with HIV infection. ANUG is also seen in children in developing countries where it can progress in the absence of treatment. In severe cases, necrosis may extend over adjacent tissues to cause gross destruction of oral and facial tissues (known as cancrum oris or noma).

Pathogenesis

The pathogenesis of periodontitis involves the interaction of plaque pathogens with the host's immune system. Considerable research is devoted to determining which, if any, specific pathogens are responsible for periodontal destruction (the 'specific plaque hypothesis'). Dental plaque is ubiquitous, but destructive disease occurs only in a minority of people. Apart from plaque, there are important determinants of periodontal disease susceptibility.

It is now clear that tobacco exerts an independent deleterious effect. Periodontal treatment is also less effective in smokers

(Reibel 2003). Stress is another risk factor: for example, greater occupational stress is associated with progression of periodontitis and ANUG has been noted among soldiers on difficult postings, students during exam terms, and people with negative life events.

Periodontitis often takes decades to become clinically detectable. While it is more common and severe with advanced years, periodontitis is not a consequence of age. It is associated with poor oral hygiene and does not progress in adults with good oral hygiene.

Treatment

For most people, the progression of periodontal destruction is compatible with the retention of a natural dentition into old age. Targets for oral cleanliness have been calculated that appear to be compatible with no or acceptably low levels of periodontal disease throughout life (Burt et al. 1985).

A significant minority of people (perhaps 5–15 per cent) may lose teeth from periodontal diseases and considerable effort is spent by dental professionals to prevent and treat them, primarily by mechanically removing plaque through regular toothbrushing and flossing of teeth. Adjunctive treatments include removal of calcified plaque (calculus), planing away the superficial layers of the roots and periodontal surgery in severe cases.

Systematic reviews are beginning to provide an evidence base for periodontal therapy although there may be considerable Hawthorne effects reflecting differences between the effectiveness of treatment provided routinely in primary care and its efficacy in clinical trials conducted in university departments. There are also few long-term studies showing effects on tooth retention.

Interventions aimed at improving oral hygiene produce short-term changes that are not sustained (Watt and Marinho 2005). Powered toothbrushes with a rotation oscillation action assist self-care although their long-term benefits on periodontal health have yet to be evaluated (Robinson et al. 2005). The most common professional procedure to prevent and treat periodontal diseases, the removal of calculus by scaling and polishing, is currently being evaluated as the available evidence was of poor

quality. There is no compelling evidence of benefits from professional mechanical plaque removal alone over simple oral hygiene instruction to prevent periodontal diseases (Needleman et al. 2005a). Another common treatment, subgingival debridement, remains untested in randomized controlled trials (RCTs), but showed modest short-term reductions in pocket depths in other controlled studies (Van der Weijden and Timmerman 2002) and a systematic review of guided tissue regeneration indicated that the mean level of attachment gained is approximately 1 mm, with eight sites needing to be treated to regain 2 mm in one site (Needleman et al. 2005b).

Oral cancer

Benign oral cavity neoplasms include papillomas, polyps, and various types of granuloma. This subsection will deal principally with malignant neoplasms, of which approximately 90 per cent are squamous cell carcinomas. They may occur on the lip, tongue, gingivae, oral floor, or elsewhere in the mouth (some statistics on mouth cancer also include the pharynx). The site is often related to the aetiological factors. Lesions may present as swellings, ulcers, or red or white patches and many are painless until they become large. Five-year survival is less than 50 per cent and depends on the disease stage at presentation. Malignant change is often seen in a number of lesions which precede tumour development and present as white or red patches of unknown origin. Malignant change is also occasionally seen in oral lichen planus and hyperplastic candidiasis.

Overall, the estimated age-standardized incidence of mouth and lip cancer worldwide for males is 5.2 per 100,000 population, with dramatic variation between and within countries (Globocan 2010) (Table 8.8.1). Men are more susceptible than women in almost all populations, independent of tobacco use.

Variations in the incidence of oral malignancy are first explained by varying exposure to three risk factors. Cancer of the lower lip is strongly associated with sunlight exposure especially in fair-skinned people. Tobacco use, whether chewed or smoked, predisposes to intra-oral cancer. The high incidence of oral cancer among southern Asians is in part due to the addition of tobacco to betel quid or ‘paan’. There are dose–response relationships for the duration of use and type of tobacco inhaled. Alcohol is an independent aetiological factor with additive effects with tobacco use. In some developed countries, oral cancer incidence correlates better with alcohol consumption and liver disease than with smoking and respiratory disease (Hindle et al. 2000).

Table 8.8.1 Oral cancer in males—age standardized rate per 100,000 population

	Rate per 100,000
Worldwide	5.2
India	9.8
United States	7.4
China	1.3

Source: data from Globocan, *Estimated cancer Incidence, Mortality, Prevalence and Disability-adjusted life years (DALYs) Worldwide in 2008*, International Agency for research on Cancer (IARC), World Health Organization, Copyright © IARC 2014, available from <http://globocan.iarc.fr/>.

In the past, oral cancer occurred mainly in older people (over 60 years). However, the incidence is increasing in developed countries because of a rising incidence in people younger than 45 years, where oral cancer may be a distinct form related to human papilloma virus (HPV) and associated with vaginal and oral sex (Conway et al. 2006; D’Souza et al. 2007). HPV-associated tumours show a predilection for the tonsils and oropharynx, and although apparently aggressive, carry a better prognosis (Fakhry et al. 2008).

Both cancer incidence and survival show distinct socioeconomic gradients. In the United Kingdom, 5-year survival for oral cancer among the most affluent was 53.9 per cent compared to 42.3 per cent in the most deprived (Cancer Research UK 2009), a difference not totally explained by smoking, alcohol drinking, and diet (Conway et al. 2010).

As early intervention improves oral cancer survival, and many cases are preceded by premalignant lesions, case finding would seem useful for disease control. However, active screening does not appear to be justified in countries with a lower prevalence and available dental services (Downer et al. 2006). Opportunistic screening as part of routine dental visits may be viable.

Trauma

Trauma to the teeth is common and frequently causes fracture of the tooth or supporting bone or bodily movement of the tooth including complete avulsion. In many cases, the long-term survival of the tooth is threatened. As the anterior and most visible teeth are most often involved, the result can be disfiguring. Worldwide, the prevalence of dentofacial trauma is approximately 10–15 per cent. Risk factors include sporting activities such as cycling and ball sports, falls, road traffic accidents, violence (including fights), and poor environments such as overcrowding. Protruding upper front teeth and inadequate lip coverage also put individuals at risk. The peak age for trauma is early adolescence with boys experiencing more injuries than girls.

Trauma to deciduous teeth is managed by monitoring, in case any consequent infection threatens the permanent tooth developing beneath it. In permanent teeth, adhesive fillings can be used to protect sensitive fractured teeth and dressings (usually calcium hydroxide) to allow continued root development in immature teeth. For permanent teeth that have been knocked out, they should be replaced in the socket as soon as possible or placed in a suitable container of milk or normal saline. Dental care should be sought immediately as tooth replantation within 30 minutes provides best long-term survival rates of avulsed teeth. The tooth should be splinted to adjacent teeth for 7–14 days and antibiotic and antitetanus treatments given. The need for urgent care means that skilled emergency dental services should ideally be available around the clock.

The cost of treating dentofacial trauma has been estimated at US\$3.2–3.5 million per million subjects (Andreasen and Andreasen 1997) and in the United Kingdom, the average total cost of treating one patient with a dental traumatic injury has been estimated at US\$1665 (Wong and Kolokotsa 2004).

Links with other diseases

Many associations between oral conditions and general health have been proposed in the last two decades.

Periodontal diseases have been linked to cardiovascular diseases, stroke, pre-term birth, and low birth weight. Some authors have even suggested that periodontal diseases are independent risk factors for these diseases. Epidemiological evidence supporting links between periodontal and other diseases suffers from many possible confounders, the potential for misclassification, and bias. Despite efforts to control for socioeconomic and lifestyle factors, residual confounding resulting from a failure to account fully for these variables seems inevitable. Specific cardiovascular risk factors such as tobacco use, obesity and lower serum high-density lipoprotein cholesterol are more common among people with high dental disease experience (Sanders et al. 2005). Some, such as tobacco smoking, are independent risk factors for both cardiovascular and periodontal diseases.

Systematic and narrative reviews of these associations have not yielded firm conclusions because of methodological complexity (Beck and Offenbacher 2005; Xiong et al. 2006; Persson and Persson 2008). The existing evidence suggests that interventions improving periodontal health do not modify these other health problems (Beck et al. 2008).

Epidemiological associations between other oral conditions and general health face the same methodological challenges. Poor oral hygiene predicted cardiovascular outcomes among Scottish adults, although the nature of the relationship was not determined (D'Oliveira et al. 2010). Having fewer teeth and not wearing dentures prospectively predicted the incidence of falls amongst Japanese elders, but again there may have been confounding (Yamamoto et al. 2012). Relationships between oral health and all-cause mortality were partly explained by covariates, but persisted after many of these covariates have been accounted for (Linden et al. 2012; Sabbah et al. 2013).

At present then, causal relationships between oral and general health appear putative and even if causal links are demonstrated, we cannot recommend oral health interventions to improve general health. For the time being, we assume these relationships are confounded by environmental and lifestyle factors common to both sets of diseases.

Inequalities in oral health

Inequalities occur in the distribution of almost all oral conditions, and this area of research and action has grown in parallel with the interest in health inequalities, led by the Commission for the Social Determinants of Health (CSDH 2008). The resultant formation of the Global Oral Health Inequalities Research Agenda (Sgan-Cohen et al. 2013) of the International Association of Dental Research will add impetus and, hopefully, practicable policies.

Oral health inequalities are related to socioeconomic status, ethnicity, or region, both in gradients and in fine grain (Anderson et al. 2012; Flores and Lin 2013). Whether socioeconomic status is measured by education, occupation, or income, these inequalities consistently relate to the degree of social inequality and not just the distribution of resources. For example, levels of total tooth loss across US states are related to the level of income inequality within each state and not just absolute levels of poverty (Bernabé and Marcenes 2011).

There are social gradients for oral cancer incidence in developing and developed countries (Conway et al. 2008), tooth loss

(Tsakos et al. 2011), the total absence of teeth, the presence of untreated decay or the presence of a filled tooth (Elani et al. 2012), more severe periodontitis (Eke et al. 2012), worse self-rated oral health, and oral impacts (Tsakos et al. 2011). Periodontal diseases are unusual in childhood and yet have been linked to the structural determinants of health more strongly than to individual factors amongst Brazilian 12-year-olds (Jordao et al. 2012). Having brown skin colour, attending a public school, and living in an area with intermediate socioeconomic indicators were associated with higher prevalence of calculus and bleeding on probing.

The life course approach indicates how people's circumstances in early life, their experiences during childhood, with their parents and family and during preschool and formal education and beyond, accumulate to influence their health throughout life. Long-term follow-ups of birth cohorts confirm the importance of this accumulated effect. In one study, 5-year-olds of low socioeconomic status had more decay, more fillings and worse periodontitis, and were more likely to have had a tooth extracted at the age of 26 years, even after controlling for childhood oral health. Furthermore, changes in socioeconomic status throughout life were associated with differing levels of oral health in adulthood (Thomson et al. 2004).

Health improvement and reducing oral health inequalities

Three increasingly important factors are shaping approaches to improve population oral health. First, the limited effectiveness of individualized approaches to disease prevention; second, the links between oral and general health; and finally, greater concern about inequalities in health.

The limited effect of individualized approaches to disease prevention

Many of the causes of oral disease relate to individual behaviours (the consumption of sugars, ineffective oral cleaning, tobacco and alcohol use, and limited exposure to fluoride). Dentistry has traditionally adopted health education as the central thrust of prevention. As with other fields, dentists have recognized that health education cannot readily change these behaviours, which are largely determined by the social and cultural environment.

Repeated systematic reviews have investigated the effectiveness of oral health promotion practices (Sprod et al. 1996; Kay and Locker 1997; Watt and Marinho 2005; Satur et al. 2010). The most robust primary studies have tended to focus on programmes in which the intended outcome was improved knowledge or modification of the behaviours of individuals, usually involving relatively short follow-ups. The main finding from meta-analysis was the effectiveness of fluoride to prevent caries (Kay and Locker 1997). A less rigorous approach (Sprod et al. 1996) still concluded there was little evaluative literature on broader approaches to health promotion. The most recent review identified evidence supporting capacity building with non-oral healthcare providers and the use of multi-strategy community-based approaches (Satur et al. 2010).

One other consideration is that preventive strategies that focus on individuals do not appear to be suitable for dental caries, periodontal diseases, and oral cancer since there are, as yet, no effective ways of identifying which individuals are at high risk of developing the diseases (Rose 1992; Watt 2007). Whilst individuals at high risk for dental disease cannot be identified easily, it is

possible to identify at-risk populations. In these situations, it can be cost-effective to target prevention at specific socioeconomic groups, particular schools or areas, with high disease incidence (Burt 1998).

Links between oral and general health

Oral health is frequently associated with general health, but only in certain circumstances is this relation causative. Instead, oral and general health conditions appear to share common risk factors that cluster in the same groups (Sanders et al. 2005), as they are distributed in the same way and follow similar socioeconomic gradients.

These epidemiological associations between oral and general health are compatible with the strategy of targeted interventions which could adopt a common risk factor approach (CRFA), tackling risk factors that are common to many conditions. The CRFA was anticipated to provide multiple benefits, reduce duplication, save resources, improve effectiveness, and reduce social inequalities. However, a recent concern with the CRFA is 'lifestyle drift' where the focus has been on behaviours rather than their upstream structural, social, and psychological determinants (Watt and Sheiham 2012). This recognition of the social context in which personal choices are made avoids the social iatrogenesis of describing oral health in individual terms (Dickson 1995).

It follows that oral health programmes should be closely integrated into programmes to improve general health for the whole population and for specific groups such as older people (Petersen et al. 2010; Satur et al. 2010). Similar observations have been made about global health policy (Dybul et al. 2012) where a focus on single diseases has ignored the problems of people experiencing multiple health problems and reinforced health inequalities.

Commission on Social Determinants of Health

Greater concern about inequalities in health has had a number of broader implications. Earlier models had seen such factors as general socioeconomic, cultural and environmental conditions and consequently people's living and working conditions as the upstream determinants of *health* (Dahlgren and Whitehead 1992). More recent models look beyond these upstream factors to consider the social determinants of *health inequalities* (Krieger 2008).

From this perspective, the social determinants of health arise and are sustained by political ecologies, power, and social relations (Krieger et al. 2012).

The CSDH adopted a conceptual framework in which a 'toxic combination of poor social policies and programmes, unfair economic arrangements and bad politics' creates a socioeconomic and political context. These structural factors shape intermediary determinants including the social position of individuals and groups (as indicated by education, occupation, income, gender, or race/ethnicity). This social position then determines the material circumstances of people, their behaviours, social cohesion, psychosocial and biological factors, and their use of the healthcare system. It is this cascade of factors that shapes the distribution of health and well-being (see Chapter 2.1).

For those concerned with improving health and reducing health inequalities, the CSDH provides a comprehensive framework for planning interventions and selecting potential entry

points, which although not specific to any particular set of diseases, is directly applicable to oral health (Kwan and Petersen 2010; Marmot and Bell 2011). The commission recommended three principles of action:

1. To tackle the inequitable distribution of power, money, and resources, and create a more equitable socioeconomic and political context.
2. To improve daily living conditions so that the material circumstances, social cohesion, psychosocial and behavioural factors, and use of health services are more equitably distributed.
3. To understand the problem and assess the impact of action.

These three activities are neither discrete nor mutually exclusive. For example, action on the distribution of power and resources will improve living conditions and work at either level will involve the same actors to a greater or lesser degree. The emphasis should be to work across all levels of the model (CSDH 2008; Kwan and Petersen 2010) and hence, at all levels of society. Systematic reviews indicate that downstream, behaviourally based interventions do not appear to reduce inequalities, and may increase them (Lorenc et al. 2013). In oral health, it has long been recognized that health education carries its own dangers of disempowerment and victim-blaming and may increase inequalities in oral health (Watt 2007). Conversely, upstream approaches such as structural workplace interventions and pricing policies have the potential to reduce inequalities (Satur et al. 2010). Conway et al.'s (2008) systematic review associated oral cancer risk with low socioeconomic status but provided evidence to steer health policies which focus on lifestyles factors towards an integrated approach to tackle the root causes of disadvantage.

One refinement of the CSDH approach is the adoption of the principle of proportionate universalism. Marmot (2010) suggested that the gradient of health inequality should be reduced by working to improve the health of all portions of society, but the scale and intensity of the action should be in proportion to the level of disadvantage, for example, by targeting particular interventions at groups at greatest risk within a whole population strategy.

To public health practitioners concerned about social injustice, the growing attention given to health inequalities is exciting. However, the likelihood of reaching a consensus and prevailing upon the power imbalances that structure the social determinants of health and consequent health inequalities may be reduced during the current global economic crisis. Moreover, inequalities appear to be increasing (Thomas et al. 2010). Health inequalities may persist because the increased social mobility of recent generations has left the lower socioeconomic groups more homogeneous in terms of the individual characteristics that predispose to ill health. It may also be that the better contemporary absolute levels of health mean that the social and individual resources associated with higher socioeconomic status are more important (Mackenbach 2012). Cumulatively, these factors require substantial effort to create greater health equality.

Actions to improve health and reduce health inequality will have similar effects on oral health but some aspects are especially relevant (Box 8.8.1). Therefore, the CSDH framework and these principles will be used in the remainder of this section.

Box 8.8.1 Improving oral health and reducing inequalities within the Commission on Social Determinants of Health framework

Tackling the inequitable distribution of power, money and resources: changing the structural drivers of conditions of daily life

- ◆ Action on health and health equity at the highest level of government with coherent policies across all departments.
- ◆ Redistributive direct taxation systems.
- ◆ Publicly funded action on child development, education, working and living conditions, and healthcare.
- ◆ Market responsibility.
- ◆ Regulation of goods and services with a direct role in health.
- ◆ Political empowerment and fair representation of all.
- ◆ Oral health impact and oral health equity audit of all policies.

Improving daily living conditions: changing the circumstances in which people are born, grow, live, work, and age

- ◆ Comprehensive approaches to early life, child survival, and early life interventions.
- ◆ Comprehensive universal social protection.
- ◆ Urban planning and fairness between areas to prevent rural poverty.
- ◆ Full and fair employment with acceptable, safe work and a healthy work–life balance.
- ◆ Access to universal healthcare.
- ◆ Increasing the availability of fluoride:
 - water
 - milk
 - salt
 - tablets/drops
 - toothpastes
 - mouthrinses
 - varnishes.
- ◆ Dietary sugars.
- ◆ Oral cleaning.
- ◆ Smoking cessation.
- ◆ Prevention and management of trauma.
- ◆ Use of oral health services.

Measuring and understanding the problem and assessing the impact of action

- ◆ Routine systems with relevant measures of oral health, its determinants, and health equity.
- ◆ Dentists and dental public health specialists as advocates.

Tackle the inequitable distribution of power, money, and resources

This part of the CSDH (2008) report makes recommendations which are the most upstream and radical, to change the way that society is organized. Action on health and health equity is advocated at the highest level of government to ensure effective and coherent policies across all departments. This work will require health impact assessment and health equity audit of all policies, using the social determinants framework across all actions of ministries of health. To ensure adequate financing for publicly-funded action, the CSDH proposed redistributive direct taxation systems, which demonstrably reduce poverty.

The provision of basic human and social needs including clean water, healthcare, and education are seen as a primary role of the state rather than the market. The state also has a role in the regulation of goods and services with a direct role in health (e.g. tobacco, alcohol, and food).

The commission also proposed that health equity be made a global development goal and that the social determinants of health be placed as a guiding principle across the WHO.

Oral health can be fitted into these broad actions on health inequalities and into all health policies. Dental workers have an important role as advocates for considering the impact of policies on oral health. For example, in many countries dental caries is now a disease of poverty and particularly of children, where redistributive taxation might reduce oral health inequalities. Work with the agricultural sector, especially in relation to the production of cash crops like sugar and tobacco, has obvious applicability to oral health. Further regulation of the production, use, and marketing of tobacco, alcohol, and sugar is also feasible at all levels of influence.

Oral diseases may contribute to social stratification as they are often visible. The appearance of the mouth is used by others to form social judgements which may limit life opportunities and employment (Newton et al. 2003). Seen this way, oral health is not only a goal but a means towards greater equality. However, to reduce the social impact of oral disease, oral health services need to be organized to meet the needs of the population. Where possible there should be universal access to primary oral healthcare services.

Improve daily living conditions

The CSDH recognized that the factors that enable good health are not distributed equally throughout life and made a series of recommendations to improve daily living conditions.

The accumulation of adversity during the life course means there must be comprehensive approaches to early life for child survival and development, and comprehensive social mechanisms to support an income sufficient for healthy living. Secure and fairly paid employment and access to universal healthcare are vital.

These actions will have direct and indirect effects on oral health. Socioeconomic status at birth was found to determine tooth loss in adulthood (Thomson et al. 2004). Early childhood caries inhibits growth and development and its treatment reverses this effect (Mohammadi et al. 2009).

One well-evaluated strategy for improving daily living conditions is increasing the availability of fluoride. Other strategies

focus on oral health behaviours, such as oral cleaning, smoking cessation, and trauma prevention.

Increasing the availability of fluoride

Fluoride prevents or reverses dental caries mainly through topical effects including the inhibition of demineralization of the tooth structure, enhancement of remineralization with a stronger crystal structure, and inhibition of bacterial enzymes. Consequently fluoride has been used to prevent caries by adding it to water supplies, toothpastes, foods, drinks, and in professionally applied products.

Water fluoridation

Beneficial effects of fluoride on dental health were inadvertently discovered during investigations of developmental staining of children's teeth in Colorado, United States, due to chronic ingestion of fluoride during tooth development.

An inverse relationship between dental caries and the fluoride concentration of drinking water was demonstrated in two ecological studies (now called the '21 cities studies'). The first intervention trial started in Grand Rapids in 1945 (Dean et al. 1950). Since then similar studies have taken place in many countries. Worldwide, around 435 million people now receive water from a fluoridated water supply and water fluoridation has been designated one of the ten most important public health measures currently available (Centers for Disease Control and Prevention 2010). Dean originally suggested that the optimal concentration for water fluoridation was 1 part per million (ppm) (1 mg/L), the recommended optimal range of fluoride is now 0.6–1.0 ppm F.

The effectiveness and safety of water fluoridation in caries prevention is consistently supported in authoritative narrative and systematic reviews. The most comprehensive systematic review, the York review, included the results of 88 studies (83 of which were cross-sectional) from 30 countries (McDonagh et al. 2000). The included studies were judged to be of low to moderate quality, mainly because of the lack of appropriate adjustment for the effect of confounding factors. Bearing in mind these concerns, water fluoridation was associated with a median increase of 14.6 per cent in the proportion of children without caries experience and a median reduction in DMFT of 2.25 teeth. For one extra child to be 'caries-free', six children would need to be exposed to water fluoridated at 1 ppm F. Water fluoridation was also found to have an effect over and above that of other sources of fluoride, particularly toothpaste.

A direct dose–response relationship was found between water fluoridation and dental fluorosis. At 1 ppm F the prevalence of fluorosis was estimated to be 48 per cent and for fluorosis of aesthetic concern 12.5 per cent. The numbers of additional people who would have to be exposed to water fluoridation at this level for one additional person to develop fluorosis of any level, was six. Other possible negative effects considered included bone fracture, cancer, Down syndrome, senile dementia, and goitre. No clear evidence of these potential effects was found, but interpretation of the results of these studies was difficult due to the quality of the primary data.

The cost-effectiveness of water fluoridation depends on the baseline level of caries and the capital costs of the necessary equipment. In areas where water is supplied to large numbers of people via a single source, fluoridation is most cost-effective.

Further high quality research into the safety, efficacy, cost-effectiveness (McDonagh et al. 2000), and impact of fluoridation on quality of life has been recommended (Medical Research Council 2002).

More recently, systematic reviews commissioned by the Australian National Health and Medical Research Council (2007) updated and supported the conclusions of the UK Medical Research Council review that strongly suggested that fluoridation of water supplies is effective in caries prevention. Water fluoridation appeared to be associated with mild dental fluorosis but there was no consistent evidence of increased association with cancer, bone fractures, or other adverse effects.

The introduction of water fluoridation schemes is invariably opposed by active anti-fluoridationist lobbies. Such groups tend to be small, but very vociferous, with considerable impact. The main arguments against water fluoridation include the safety concerns outlined earlier and ethical objections that fluoridation of water supplies infringes on individual freedom of choice and removes the right of adults to refuse medical treatment. Fluoridation is portrayed as 'mass medication'. The ethical objections to water fluoridation have been discussed by applying the four principles that encompass most of the moral aspects of healthcare, that is; respect for autonomy, beneficence, non-maleficence, and justice (Jones and Lennon 1997).

With regard to the claims of loss of autonomy, those proposing fluoridation suggest some reduction of individual freedom is accepted for the overall good of the community. On the argument that only dentate members of society will potentially benefit from water fluoridation, those in favour acknowledge this but fluoridation will 'do no harm' to any members of society. On the principle of justice, some claim that imposing water fluoridation is not fair on those against it. Proponents counter this argument by suggesting that the reduction in inequalities in dental health that fluoridation potentially provides is a just way of helping those least able to help themselves.

The debate about fluoridation is an interesting one. Anti-fluoridationists tend to come from relatively healthy middle-class groups. As children in these groups have the lowest caries experience, they have the least to benefit from the intervention. Unfortunately, their effect is to maintain social inequalities in health.

Water fluoridation has tended to be a sacred cow within dental public health; something to be embraced and considered immune from criticism. A more recent alternative view sees water fluoridation as modestly effective in developed countries with low caries (as demonstrated by the relatively high number needed to be treated to prevent a case), yet the political battle for new fluoridation schemes may make it very expensive to introduce.

Other vehicles for administering fluoride include the following:

- ♦ *Fluoride milk:* fluoride has been added to milk as an alternative to water since the 1950s in many countries. These schemes vary in the age at which children start drinking the milk, the number of years over which it is administered, the number of days a year the milk is consumed, and the concentration of fluoride added (Marino et al. 2006). Systematic reviews of the effectiveness of fluoridated milk for preventing caries present mixed conclusions, in part because of varied quality of the available data. The results are consistent with a caries preventive effect

with cessation being associated with increasing caries incidence (Yeung et al. 2005; National Health and Medical Research Council 2007).

- ♦ **Salt fluoridation** was first used in Switzerland in the 1950s. In certain cantons and in some Latin America countries, all salt for human consumption is fluoridated. Other European countries including France only sell fluoridated salt for domestic use. The typical concentration is 250 ppm F. Several cross-sectional studies report fluoride salt to be effective at reducing caries (Jones et al. 2005).
- ♦ **Fluoride tablets/drops** use also began in the 1950s. They have been used as dietary supplements with different countries having different dosing regimens (based on child's age, weight, caries-risk, fluoride in the water). Their effectiveness has not been confirmed by any well-designed trials or systematic reviews and the available studies fail to account for confounding factors. There is some evidence that when sucked to maximize the topical dose, a preventive effect is observed in deciduous teeth. Two key problems with fluoride supplementation are adherence to dosing regimens and the risk of fluorosis. Many of the people most susceptible to caries find the dosing schedules difficult to maintain. Taken as a daily bolus, fluoride supplements increase the risk of fluorosis (Ismail and Bandekar 1999). These concerns have led to a reduction in the use of tablets/drops as a public health measure.

Topically applied fluoride

Includes delivery systems where fluoride is applied to tooth surfaces at high concentrations for a local protective effect. A series of systematic reviews of trials have investigated the effectiveness of various topical fluorides expressed as the preventive fraction (the difference in caries increments between the intervention and control groups expressed as a percentage of the increment in the control group) (Table 8.8.2).

- ♦ **Fluoride toothpaste** Toothpaste is the most widespread source of fluoride and the decline in caries experience in children in some countries has been attributed to its regular use. The fluoride compounds and concentrations found in toothpastes

vary between brands and between countries. The usual concentration is 1000–1500 ppm F with higher (over 2000 ppm F) formulations available. They present a good vehicle for the frequent low-dose application of fluoride and their effectiveness in reducing caries in children has been confirmed with a prevented fraction (PF) of 24 per cent (Marinho et al. 2003a). The risk of fluorosis from toothpaste can be minimized by using a smear of paste and supervising children under 6 years of age.

Fluoride toothpaste has a distinct disadvantage over water fluoridation as a broad preventive strategy as it relies on people brushing their teeth. In developed countries infrequent brushing and high caries incidence are *associated* and so the people who have most to benefit from the use of fluoride toothpastes are less likely to use them frequently. In developing countries there may not be a tradition of tooth cleaning with toothpastes and Western proprietary brands are likely to be expensive. However, cheap locally made pastes can be profoundly effective (Yee et al. 2003).

- ♦ **Fluoride mouthrinses** Fluoride mouthrinses have been used extensively for the past 30 years. School-based programmes were common in certain countries although individual home use now predominates. Mouthrinsing is not recommended for children under 6 years of age, due to the risk of fluoride ingestion. The two main concentrations available are 0.05 per cent (230 ppm F) sodium fluoride used daily and 0.2 per cent (900 ppm F) sodium fluoride weekly. The effectiveness of mouthrinses in children has also been confirmed with a PF of 26 per cent (Marinho et al. 2003b).
- ♦ **Fluoride varnishes/gels** Topically applied fluoride varnishes and gels have been used widely for over two decades, both as part of community-based programmes and on an individual basis. Fluoride varnishes are professionally applied, with the two most commonly used varnishes containing 22,600 ppm F or 7000 ppm F. A systematic review of trials has shown the effectiveness of topical varnishes, although the included studies were of poor quality. The PF in permanent teeth was 46 per cent (Marinho et al. 2002a). However, a more recent cluster RCT of a school-based fluoride varnish programme in the United Kingdom was unable to demonstrate an effect to prevent caries in first permanent molar teeth over a 3-year period (Milsom et al. 2011).

Fluoride gels can be professionally or self-applied under supervision. The most commonly used gel is a professionally applied 12,300 ppm F acidulated phosphate fluoride. Due to the risk of excessive ingestion, this gel is not recommended for young children. The effectiveness of professionally-applied and self-applied gels have been reviewed with a PF of 28 per cent (Marinho et al. 2002b).

Behaviours

Dietary sugars

Dietary sugars are a necessary cause of clinically relevant dental decay. Unfortunately, repeated systematic reviews indicate that dietary advice neither reduces their intake nor the incidence of caries (Sprod et al. 1996; Kay and Locker 1997). Health education programmes only appear to be effective if they also involve the recommendation or prescription of fluoride vehicles.

Table 8.8.2 Relative effectiveness of sources of topical fluoride

Source	ppm F	Prevented fraction (%)
Toothpaste	500–1500	24
Mouthrinse	230–900	26
Varnish	7000–22,000	46 (permanent) 33 (deciduous)
Gel	12,300	28

No.: CD002284, Copyright © 2003.

However, the data suggest that restriction of dietary sugars by other means is preventive. For example, per capita sugar supplies and caries experience data correlate significantly in national ecological comparisons. A children's home in Australia had a dietary regimen with almost no sugar and the children had very low caries levels until they were allowed to make their own food choices at the age of 12. Likewise, caries levels fell in parallel with the availability of sugars during the Second World War (Rugg-Gunn 1993).

It is difficult for people to restrict their consumption of sugars. There are evolutionary reasons for sweet foods and drinks to be pleasant. Consequently 'hidden' sugars are used to make processed foods nicer. In addition, products used to sweeten foods may not be labelled as such, even if they carry similar risks of harm (e.g. fructose corn syrup). To add to this confusion, ecological and animal studies indicate that sugars in whole fruit (sometimes called intrinsic sugars) do not cause caries. Furthermore, intrinsic sugars have a relatively low glycaemic index and are accompanied by fibre and so are not usually associated with obesity.

A health-directed food policy focusing on the supply of products containing unhealthy sugars seems logical, and is likely to impact on dental diseases as well as broader health problems, given the growing evidence implicating them as a cause of obesity, myocardial infarction, dyslipidaemia, pancreatitis, and hepatic dysfunction (Lustig et al. 2012; Willett and Ludwig 2013). The WHO recommends countries to formulate their own specific goals to reduce the amount of free sugars, with a maximum of no more than 10 per cent of energy intake (it is approximately 15 per cent in the United States and United Kingdom). In addition, the frequency of consumption of foods containing free sugars should be limited to a maximum of four times per day.

Such policies should form part of a broader strategy to reduce dietary intakes of refined grain products and potatoes. Possible strategies fall within the framework of education, substitution, regulation, pricing, or provision (Watt and Rouxel 2012). Multi-levelled fiscal policies can be used to discourage the manufacture and sale of sugar-containing products, including taxing sugar-containing foods and drinks and restricting advertising to children. Beyond approaches aimed at individuals, education can take the form of authoritative dietary guidelines to inform national policies, community initiatives, and caterers. Recommendations by the Finnish National Board of Education reduced the sale of sweet products in Finnish Schools (Kankaanpää et al. 2012). Healthcare workers can routinely ask their patients about sugar consumption (dentists do this all the time!). All of these approaches and direct consumer pressure can help convince caterers and retail outlets to provide food in a way that makes the healthy choices the easier choices.

Dietary sugars can be substituted with artificial sweeteners to reduce caries incidence. Sales of sugar-free carbonated drinks in Europe and North America demonstrate the compatibility of this measure with commercial interests. However, substitution of dietary sugars has only limited potential because the manufacture of many foodstuffs relies on other specific properties of sugars. In addition, some sweeteners have side effects and resistance to the extended use of artificial sweeteners persists.

Oral cleaning

As plaque is a necessary cause of periodontal diseases it seems logical that tooth cleaning (principally by toothbrushing)

should be the cornerstone of their management and prevention. Interventions aimed at improving oral hygiene can be successful and achieve a commensurate reduction in gingival inflammation (Kay and Locker 1997; Watt and Marinho 2005). However, most studies have had short follow-up periods and the effectiveness of even the best interventions diminishes with time. Therefore few data show that attempts to improve oral hygiene to prevent destructive disease are effective. Nonetheless, the consensus is that the public health approaches to improve periodontal health should include improved oral hygiene.

The relationship between plaque removal and tooth decay is much more contentious. In a carefully designed trial, professional oral cleaning did not demonstrate any additional preventive effect above a standard preventive programme of fissure sealants and locally applied topical fluoride (Arrow 1997). Sutcliffe (1996) reviewed the effect of research methods on the observed relationship between oral cleaning and dental caries and concluded that there was 'no unequivocal evidence that good oral cleanliness reduces caries experience'. This area of research is fraught with difficulty as apart from the difficulties of measuring dental disease, studies are susceptible to selection bias, leakage of intervention, and the likely confounding effects between self-reported behaviours, diet, and oral hygiene. Studies where professional cleaning has been effective have used pastes containing fluoride. What is known is that brushing with fluoride toothpaste is effective in preventing caries. Therefore brushing as it is currently practised in most developed countries combats both caries and periodontal diseases and is to be encouraged.

The systematic reviews cited earlier demonstrated that it is difficult to achieve sustainable changes in oral hygiene behaviour. One approach has been to teach toothbrushing to both make one feel and look nice and as part of a positive and healthy lifestyle. Toothbrushing is a habit learned as a young child and is difficult to change later in life, hence interventions via healthcare workers and social agencies working with young children and their parents may be useful.

Toothbrushing often clusters with other health behaviours such as tobacco use, exercise, healthy eating, and other aspects of hygiene such as hand washing. In turn, these behaviours may relate to personal factors including greater self-efficacy, self-esteem, having confidence in one's family, life satisfaction, managing in school, and not having other health problems. Unsurprisingly then, toothbrushing is determined by structural and resource-related factors and living conditions. These factors include family structure, social support, external barriers, domestic arrangements, social norms, cultural factors, socioeconomic status, and socioeconomic development. Therefore actions across all these levels are most likely to improve periodontal health and periodontal health equity.

Smoking cessation

Cessation of smoking decreases the associated elevated risk of oral cancer within 5–10 years. Numerous other oral conditions are directly or indirectly associated with tobacco smoking. Many of these, such as stained teeth, receding gums, and altered taste are readily perceptible to the individual and may encourage or reinforce the desire to stop smoking. The dental team are also often aware of the personal and social circumstances (e.g. pregnancy or a new job) that prompt people to give up. The dental team can

hence support smoking cessation by providing advice (Carr and Ebbert 2006).

Trauma: prevention and management

Maxillofacial trauma is related to environmental and structural factors such as socioeconomic status, alcohol use, and road planning and use. In children, dental trauma is closely related to area-based measures of socioeconomic status and overcrowding. Many of these factors can be alleviated by improving living conditions.

Local and individual strategies can also help reduce trauma to the face and teeth. Playground surfaces can be made of impact-absorbing materials which cushion against trauma. The use of mouthguards is compulsory for some sports in some countries. Mouthguards not only prevent dental injuries, but also prevent laceration of the facial soft tissues against the teeth, reduce the risk of mandibular fracture, and may protect the cranial cavity. The most basic type may be obtained prefabricated in a range of sizes. A more sophisticated type may be adapted to fit the mouth, typically by softening it in hot water first. Custom-made devices are the most comfortable and can be made to support the lower teeth and mandible during trauma.

Immediate first-aid for dental trauma (particularly teeth that have been knocked out) is critical to preserve the traumatized teeth. Informing athletes and their teachers and trainers of the need for immediate action can reduce the impact of the trauma.

Unfortunately orthodontic treatment of protruding front teeth is complex and prolonged, but can be justified in children of 8 or 9 years to reduce the risk of trauma.

Use of health services

The biomedical model remains the dominant approach within dental services despite the widespread recognition of the relatively small contribution of healthcare and dental care to health (Illich 1976; McKeown 1976) and oral health (Nadanovsky and Sheiham 1994, 1995). Orthodontic treatment is often advocated on the basis of social and psychological benefit. However, a 20-year follow-up study was unable to find evidence to support such a benefit (Kenealy et al. 2007). Many interventions used in dentistry (Baelum 2011) often involve cycles of placing and replacing fillings. As the quality of many fillings is not high and even the decisions to place fillings are idiosyncratic (Elderton and Nuttall 1983), the replacement of fillings several times over a lifetime leads to increasing damage to the remaining tooth.

Similar problems exist with medical and dental care. Resources are constrained and may be poorly allocated. Services still cluster around people who can afford them, while those who cannot have little control over their own health and healthcare. In every country of the world, there are people who cannot attend and/or afford dental treatment, and even in well-developed socialized systems of dental care, major inequalities exist (Watt and Sheiham 1999).

Views about the relative role of health services remain polarized. From one perspective, too narrow a focus on 'health service issues' contributes to the failure of public health to improve population health (Holland 2002; Beaglehole and Bonita 2004). The 'post-new public health' view argues that preventive and curative measures prolong life expectancy and maintain and improve the quality of life. Bunker (2001) estimated the increases in life expectancy attributable to clinical care from declines in disease-specific death

rates and from specific treatments. His conclusions may have been optimistic as he generalizes results achieved in research trials to routine practice, and underestimates the role of social and other environmental factors in health (Frankel 2001; Tudor Hart 2001).

At a population level, it remains difficult to distinguish the effects of medical care from those of other health determinants. At a practical level, such a distinction may not ultimately be critical since the key is to select the interventions that can improve the health of the population (Frankel 2001).

Unfortunately, when compared to medicine, the benefits and costs of clinical dentistry at either an individual or population level are relatively unknown. However, there are some good examples of developments in the evidence base for different aspects of dental services. One such example is that of screening for dental caries in schools, an activity that is undertaken in various forms in many countries. An RCT conducted in England examined three different models of school screening and found none were effective at reducing levels of active caries and increasing attendance by children at the dentist (Milsom et al. 2006). This study led the UK screening committee to change its policy, and recommend school dental screening be stopped and the resources redirected at oral health promotion activities. Caries screening programmes that provide treatment to children directly after detection of the disease appear to be more effective.

Public health specialists can help increase the effectiveness and equity of access of services. For example, clinical dentistry can have a role in reducing the psychosocial impacts of oral disease (Awad et al. 2000; Robinson et al. 2005). For this reason, it is essential to identify more relevant measures of oral health to assess treatment need and the outcomes of care. The evidence-based approach, the use of clinical governance, and managed care should provide both the impetus and means to ensure that only effective and efficient interventions are used.

Specific changes that could be made to ensure access to dental services can still be categorized in the framework used by Penchansky and Thomas (1981). Services must be available, accessible, affordable, acceptable, and accommodating. This framework is broadly compatible with the characteristics of dental services as seen within Andersen's (1995) behavioural model of access.

Clearly people cannot use services that do not exist, so increasing their availability has a direct effect on service use. In addition, the heterogeneity of dental health in the developed world means that older people (the 'heavy metal generation') will continue to have complex dental treatment needs for decades to come, whereas the needs of younger people are likely to be more straightforward. The proportion of dental treatment that falls within this straightforward category will continue to grow. It is not cost-effective for broadly trained and highly paid dentists to undertake this less demanding and repetitive work. One approach is to delegate more straightforward treatments to other DCPs, especially in deprived communities, hence liberating dentists' time to undertake more complex treatments.

A number of countries including Australia, New Zealand, Canada, and the United Kingdom employ DCPs with a limited repertoire of treatment options (variously called school dental nurses, dental auxiliaries, and dental therapists). The scope of practice of dental therapists varies from country to country (Nash et al. 2012). In general, they may undertake diagnostic procedures and treatment planning and preventive services, place fillings in

primary and permanent teeth, and extract primary teeth. They may also be permitted to extract permanent teeth. The appropriateness of these skills to the treatment needs of their populations and the relatively low cost of training and employing dental therapists means that their use is growing in some countries and being considered in others, including the United States.

Therapists can be used to increase access to care by supplementing the volume and reach of services, which enhances equity (Dyer et al. 2013). Therapists are socially acceptable where they are integrated into existing dental systems. Available data suggest that therapists offer care that is similarly effective to that provided by dentists. Substitution of dentists by therapists within small dental teams creates complexities and costs that reduce efficiency. Conversely, efficiency appears to be high if therapists work independently. However, dental organizations tend to prevent or restrict the deployment of therapists. For example, executives of the American Dental Association have advocated a free market dental system with subsidized treatment for disadvantaged families rather than a needs-based system using DCPs in areas with an undersupply of care (Bramson and Guay 2005).

In developing countries with a growing incidence of dental caries which may not be able to afford sufficient dentists to meet the needs of their populations, dental professionals may be an appropriate solution.

One particular aspect of dentistry in many countries that could be revised is the direct fee-for-service system of payment to dentists. Fee-per-item service payments encourage dentists to work quickly and may incentivize over-treatment and not prevention unless there is a specific fee for this. On the other hand, services based on capitation per patient enrolled reduce restorative treatment and increase preventive care with no evidence of 'supervised neglect' (Johansson et al. 2007).

The acceptability of dental services was highlighted in a qualitative study of people who did not go to the dentist (Gregory et al. 2007). As well as being influenced by the perceived accessibility of care, participants were swayed by their trust in dentistry and their perceptions of oral health as a commodity. For these people at least, greater marketing may have been counterproductive in encouraging use of dental services.

Dental services in middle- and low-income countries

Non-industrialized countries usually suffer from resource constraints including workforce, appropriate technology, and reliable power supplies. For example, the dentist:population ratio in many countries in Africa is less than 1:100,000 population compared to 1:1100 in many Scandinavian countries. This is exacerbated by the migration of dentists from middle- and low-income countries to more developed countries. For example, over a quarter of dentists in the United Kingdom were not UK-born and two-thirds of dental graduates from the Philippines migrate to the United States although most do not work there as dentists.

The limitations of the traditional curative approach to dental health are more extreme in the context of the developing world. The surgical approach to dentistry is technology intensive and requires the availability of continuous power and water supply. It involves expensive equipment that is difficult to use and maintain. Dentists, therefore, need to treat patients who can help them recoup their costs. These pressures limit the availability of services

and contribute to the inequalities in their provision. Large parts of the Western model of dental care may be inappropriate in developing countries, including an overemphasis of clinical surveys in healthcare planning. Services based on normative assessment limit community participation in healthcare and ignore the sociodental implications of oral disease. In one notorious example, survey data used to calculate the periodontal treatment needs of children in Kenya (Manji and Sheiham 1986) would have used the entire national dental workforce for up to 21 years. Services could concentrate on the relatively few conditions that comprise the bulk of oral health problems: toothache (not *tooth decay*), trauma, oral infections, and neoplasms (Hobdell 1993).

The primary oral healthcare approach (PHCA) is still relevant in all countries but particularly so in the developing world. It has five principles:

1. *Equitable distribution of services*: Tudor Hart's (1971) 'inverse care law' between the availability of services and the need for them also occurs in dentistry. It is particularly extreme in countries where there are wide disparities between rich and poor. In Africa, 80 per cent of the trained professional personnel live and work in affluent neighbourhoods in cities although the same proportion of the population lives in rural areas. The scope for other dental care professionals in developing countries may be greater since political lobbies of dentists may be less well established than in industrialized nations. DCPs can provide simple, but essential treatments to extend the availability of services and reduce inequalities in access. Models exist for identifying the types of personnel needed for oral healthcare in deprived communities along with training and evaluation methods (Samarawikrama 1995).
2. *Community involvement in health*: this means that people are allowed to take control of their own health and is necessary if programmes are to thrive. It is perhaps the most difficult aspect of the PHCA since it requires health professionals to relinquish their traditional hierarchical role. Individuals and communities often also regard health as beyond their control and may not consider oral health a priority. There are isolated examples of wide involvement in oral health. In Glasgow, Scotland, community-based Oral Health Action Teams (partnerships of parents, teachers, nursery nurses, health visitors, and dentists) have reduced caries levels in young children in deprived areas of the city (Blair et al. 2004).
3. *Focus on prevention*: prevention of oral diseases is universally accepted as an essential component of care, but in the past has involved people as passive recipients of information rather than active participants in health promotion. Systematic reviews suggest that programmes to optimize exposure to fluoride are the most effective.
4. *Use of appropriate technology*: 'appropriate technology' does not connote 'cheap' and 'second rate', but an approach which recognizes the needs and resources of the local community. For example, ART combines these requirements with knowledge of dental caries progression and developments in dental materials science.
5. *Multisectoral approach*: we have seen how an effective health strategy might involve a number of departments of both national and local governments, water providers, the educational system,

community members, and healthcare workers. All of this needs to be integrated coherently to go beyond just using the resources of other sectors to promote oral health. For example, if dentists simply get teachers to provide dental health education, this carries the risk of not truly involving the other sectors (Mautsch and Sheiham 1995).

Measure and understand the problem and assess the impact of action

Monitoring the social determinants of oral health requires routine systems to record relevant measures of health, its determinants, and health equity. Such data can be collected during dental treatment or through surveys.

New evidence on the role of social determinants in oral health equity and evaluations of interventions to reduce inequality should emerge from the international emphasis given to the topic. For example, WHO attention on the social determinants of health should make funding for such work a priority. One area where the global oral health inequalities research agenda can make an immediate impact is to provide a forum for sharing and interpreting new evidence.

Training on this topic is available through undergraduate and postgraduate courses for dentistry, although the extent and focus varies. The WHO Oral Health Programme provides guidance on tackling oral health inequalities, but could benefit from greater resources (Kwan and Petersen 2010).

Future developments

Several trends in oral health have been observed. First, some countries, particularly developing ones, may experience increases in dental caries due to the adoption of diets high in sugars. These trends are worrying even if they are limited to more affluent city dwellers as the increase in treatment needs is likely to place an unaffordably high burden on developing economies while this burden will be moderated by the low levels of perceived need in communities unused to receiving dental treatment. However, if disability and handicap from oral disease is to be minimized, then appropriate treatment is necessary. Numerous examples now exist of DCPs being used to provide a limited range of treatments in both the developed and developing world. DCPs can be trained quicker to provide care to similar standards to dentists, but at greatly reduced costs. Food and health policies could also be used in countries with rising caries levels to control imports and the production and sale of cariogenic foods, and drinks while encouraging the use of traditional foods, although the evidence base for the effectiveness of the use of such policies is weak.

Second, the fall in caries prevalence seen in developed countries over the past 40 years appears to have slowed, with evidence of wide inequalities between those living in the most and least deprived areas. Several studies have suggested that not only do people living in deprived areas have more dental caries, the disease has more impact on their daily lives.

Third, in many developed countries the combination of demographic changes, changed attitudes towards oral health, and the preservation of teeth produces an interesting pattern (Fig. 8.8.1). The growing number of older people who will live longer and retain many heavily restored teeth will increase the need for more care, some of it more complex, which in turn will drive more specialization.

The deprofessionalization of dentistry that has continued for the last decade appears to be gathering pace and is manifest in several different forms. In many developed countries patients are demanding 'rights' as consumers of care, even as marketing theory is being applied to dentistry, which places consumer satisfaction as being essential for business success. Similar principles are cornerstones of new public health. Health promotion takes public involvement in oral health well beyond clinical dentistry. Even within clinical care, satisfaction is an integral part of the process of care rather than just an outcome. Other agencies, such as governments and insurance companies, are increasingly involved in healthcare. Externally applied measures to minimize the costs of care and increase the accountability of healthcare organizations whilst assuring the quality of care all serve to reduce professional power within dentistry.

Gigerenzer and Gray (2011) have named the twenty-first century as the *century of the patient*. They envisage a critical mass of increasing health literate and numerate patients triggering healthcare improvements. The improvements will come about because healthcare workers will need to be better informed to keep up with their patients. They suggest widespread stakeholder participation to solve common healthcare problems using all the theoretical and practical knowledge available.

This trend of deprofessionalization is likely to continue and may help to make oral care more relevant to the needs of the people it serves. Deprofessionalization and greater lay involvement in dentistry, both at the individual and community level, will reduce the power structures and hierarchies that underpin the social determinants of health. This might be particularly important where perceived social position is a cause of health inequality independent of objective assessments of socioeconomic status (Sanders et al. 2006). Given that professions are likely to resist any tendency to undermine their power, there is an opportunity for dental public health to facilitate and manage the deprofessionalization of dentistry.

Evidence base

Only a minority of practitioners and academics appear to be contributing to the growth in the evidence base of dentistry. Those practitioners conduct a growing number of systematic reviews, but unfortunately these repeatedly conclude that there is a dearth of good primary data on which decisions can be based. Whilst a greater evidence base for individual care is needed, more research is urgently needed on the benefits of interventions at a population level, not only to improve health, but also to reduce inequalities.

Other chapters in this text will consider the evaluation of health promotion in some detail (see Chapter 2.1), but the debate about controlled trials in public health continues. Health promotion takes place in the 'real world' and other factors and time intervene between the intervention and health outcomes. For example, implementing a life course approach to reduce inequalities may take decades before its benefits are manifest. These factors have led the WHO (1998) to conclude that 'The use of RCTs to evaluate health promotion initiatives is, in most cases, inappropriate, misleading and unnecessarily expensive'. Even the keenest advocates of RCTs acknowledge that they are unsuitable for evaluating legislative and policy changes (Rosen et al. 2006). However, many of the problems often cited against conducting trials in public health can be overcome (Macintyre 2011).

Technology

Technological developments may also influence oral health and care. In developed countries, osseo-integrated implants are increasingly used to support dental prostheses. By providing a stable and retentive base for both single and multiple tooth prostheses, implants show great potential for reducing the handicap brought about by oral disease (Awad et al. 2000). At present, however, implant treatment demands considerable specialist expertise, requires regular maintenance, and is costly. Implants may therefore become a treatment limited to those who can afford them and thus contribute to inequalities in oral health. Other more long-term technological possibilities include a vaccine for dental caries, growing teeth from stem cells, the use of nanotechnology, and laser drills.

Cosmetic dentistry

As dental disease has declined in developed countries the technology that allowed restoration of damaged dentitions is now available for purely cosmetic purposes. Cosmetic dentistry procedures include bleaching teeth and the use of veneers to change their appearance. There is little evidence that dentistry to improve appearance can bring about psychological or social benefit. Therefore, cosmetic dentistry may improve appearance but not health.

Cosmetic dentistry can be seen as the medicalization of beauty and as a form of iatrogenesis. Supplier-induced demand is evident when dentists draw patients' attention to minor dental anomalies (that may have no effect on their lives) and suggest they have them corrected. Attractiveness is perhaps more important now than ever before and society is said to be suffering from a normative discontent with personal appearance. Dentistry may contribute to these problems if the availability of treatment to enhance dental appearance makes deviations from the norm less acceptable. This message is amplified in printed and broadcast media that expose us to enhanced images. Photographs in magazines have whiter and straighter teeth than would normally be encountered and exposure to these images increases our dissatisfaction with our own appearance. In addition, cosmetic dentistry will only be available to those who can afford it. It may be that the visible consumption of cosmetic dentistry will further distinguish socio-economic groups and so contribute to the stratification of society and social inequalities. From this perspective, cosmetic dentistry might have adverse effects both on the people who receive it and on wider society and consideration may be required about whether its growth should continue unchecked.

Consumerism and the role of industry in oral health

Consumerism is widely criticized from the perspective of over-consumption, its links with media culture, and from socialist and feminist perspectives. Its role in oral health is not so clear cut. The addition of fluoride to toothpastes has been one of the most successful dental public health interventions of all time. The effectiveness of fluoridated toothpastes is demonstrated in a Cochrane systematic review of RCTs (Marinho et al. 2003a). However, the effect is cumulative and is staggering when seen over decades. The first fluoride toothpastes were introduced in the 1950s but sales rose dramatically in the United Kingdom during the 1970s (the proportion of toothpaste sales containing fluoride rose from

less than 10 per cent in 1970 to more than 90 per cent in 1976). This chapter has already described the beneficial impact which continues throughout the lifetime as demonstrated by the growing cohorts of people with more sound and unfilled teeth in Fig. 8.8.1.

Although dentists were involved in the development, evaluation, and promotion of fluoridated toothpastes, it was the commercial interests of home-care product manufacturers which drove this development. There are also numerous examples of manufacturers and dental organizations working together to promote oral health that continue to this day.

The commercial marketing of dental care products has other advantages. It has raised the prominence of oral health and reinforced the idea of frequent oral cleaning as a social norm. In addition, the positive ways in which oral healthcare products are advertised has made a healthy mouth seem attainable.

Conclusions

In summary, we have argued that poor oral health is a major public health problem with a huge population burden of oral disease because of the large numbers of people affected. Whilst the incidence of dental caries has fallen in the developed world, the prevalence of the condition would be staggering when compared to any other disease. Periodontal diseases, cancer, and trauma all pose specific problems. All these diseases have significant impacts and create a considerable burden to both individuals and the community. The links between oral and general health indicate that strategies to improve both sets of problems and reduce inequalities should be integrated within the framework advocated by the CSDH. Several factors, including tighter financial pressures, trends in oral health, the deprofessionalization of dentistry, the role of consumerism in oral health, and the need for a better evidence base will modify this endeavour, as will the growth of skill mix, technology, and cosmetic dentistry.

Musculoskeletal disorders

Lope H. Barrero and Alberto J. Caban-Martinez

Introduction to musculoskeletal disorders

Musculoskeletal disorders (MSDs) refers to a large variety of health conditions that affect muscles, tendons, ligaments, nerves, and bones. Conditions such as osteoarthritis (OA), osteoporosis, low back pain (LBP), rheumatoid arthritis (RA), and carpal tunnel syndrome fall into this large category of health conditions.

Multiple factors related to the intrinsic characteristics of individuals, their environment, and their daily activities can contribute to the occurrence and burden of MSDs. The relative contribution of these factors can vary across populations in different parts of the world. As we learn more about the mechanisms through which these conditions occur, we have been able to improve our understanding of how multiple complex pathways can take a person from a healthy status to a disease state. This new knowledge about the diagnosis and pathogenesis of MSDs has emphasized the fact that in reality, MSDs can include several very different conditions, which in essence implies that no single pathway for diagnosis, treatment, or rehabilitation can be effective, not even in very well-defined specific populations.

The importance and major public health burden of MSDs is rooted in the fact that these conditions occur more frequently than many other conditions that can affect human health; and when they do occur, they tend to last longer than other conditions, and coexist with other, sometimes deadly conditions that are caused by the same factors or that are complications resulting from them. For example, in the United States, approximately 50 million adults have a doctor diagnosis of arthritis, yet 1.2 million, or nearly one in four adults with arthritis (24 per cent), also have heart disease (Cisternas et al. 2009). These characteristics translate directly into a large burden to society that can appear in the form of direct health services costs, reduction in opportunities for those affected, and suffering for those affected and their families. Furthermore, because of the differences in access to healthcare, the burden of these conditions may vary substantially between different latitudes, generating questions about equality and social justice.

In this chapter, we first present a brief description of some of the most important MSDs of public health importance. We then briefly describe what we know about their causes and what is already known about how to prevent them or reduce their impact to society. We will also describe the scope of the problem from a public health perspective. We present a brief account on the epidemiology of these conditions; the estimated costs to society; and the most important barriers that prevent people from obtaining

some relief. Lastly, we summarize recommendations for public health policy action and for future research.

Definition and classification of musculoskeletal disorders

There is a broad scope of health conditions that comprise MSDs including inflammatory conditions such as gout and RA, age-related diseases such as OA and osteoporosis, conditions with ambiguous aetiologies such as fibromyalgia and LBP, conditions due to injuries from occupational exposures, sports injuries, as well as injuries resulting from slips, trips, and falls. While some of these conditions present with acute onset and short duration, a larger proportion of these disorders reoccur or become lifelong health conditions (Woolf et al. 2010). These conditions can substantially impair both mental (Carder et al. 2013; Holmgren et al. 2013) and physical function and therefore are a major determinant of the health of populations worldwide.

Different classifications of MSDs can be found in the scientific literature based, for example, on body part affected, whether it has a systemic origin, or based on the external causal factor (e.g. whether it is work related or not).

The International Classification of Disease, tenth revision (ICD-10) (World Health Organization (WHO) 2010, chapter XIII) provides a useful framework with which to classify diagnostic groups of MSDs and they include:

- ◆ *Arthropathies*: disorders predominantly affecting limb joints including those due to microbiological agents (e.g. RA, juvenile arthritis, gout, psoriatic spondylitis).
- ◆ *Systemic connective tissue disorders*: including autoimmune disease and collagen (vascular) disease (e.g. systemic lupus erythematosus and sicca syndrome (Sjören's syndrome)).
- ◆ *Dorsopathies*: disorders of the spine including deforming dorsopathies, spondylopathies and other dorsopathies (e.g. cervicalgia, sciatica, and LBP).
- ◆ *Soft tissue disorders*: disorders of muscles (e.g. muscle strain).
- ◆ *Osteopathies and chondropathies*: including disorders of bone density and structure (e.g. osteoporosis); and chondropathies (e.g. juvenile osteochondrosis).
- ◆ *Other disorders*: including conditions nowhere else classified including post-procedural MSDs and biomechanical lesions not elsewhere specified.
- ◆ *Additional MSDs may be found among other groups of diagnosis*: MSDs involving nerve damage (e.g. carpal tunnel syndrome)

can be found among diseases of the nervous system. Also, MSDs involving sprains and strains for joints and ligaments can be found in the injury category.

Major musculoskeletal disorders: case definitions, natural history, pathophysiology, risk factors, and treatment

While there are many types of MSDs, musculoskeletal tissue degeneration in general can be initiated by systemic disease, trauma, and repeated biomechanical strain—all of which can lead to disability and pain. For example, autoimmune diseases can initiate and sustain damaging processes to body tissues including musculoskeletal tissue (Smolen and Aletaha 2008). Similarly, hormonal imbalances can generate loss of structure in bones and result in osteoporosis. On the other hand, trauma resulting, for example, from a fall at an early age, can initiate abnormal processes of gene expression or result in incomplete repair processes that end up affecting musculoskeletal tissue structures. Also, repeated loads can result in tissue micro-trauma that affects its function and eventually accumulates to major damage if recovery is not allowed.

Environmental factors (e.g. eating and physical activity habits) and individual characteristics (e.g. genetic factors and age) are determinants of MSDs (Gabriel and Michaud 2009), influencing the initiation and development of the disease process through complex relations. For example, poor eating habits can result in overweight individuals, which can affect the biomechanical loading on joints and hence lead to OA conditions (Guilak 2011; Vincent et al. 2012). Similarly, genetic factors can be involved in the onset of systemic inflammatory disease and can also influence body response at different stages of the disease process. On the other hand, ageing activates several different biochemical processes of tissue degeneration through insufficient expression of tissue components or the occurrence of other age-related diseases with the capability to influence the process of tissue degeneration.

Tissue degeneration is thought to accumulate throughout the life course, although determining the beginning of the disease process is difficult. The accumulated damage can be seen clinically based on radiographic or serologic evidence. For example, tissue tears and tissue deformation can be seen based on imaging techniques. A large body of research has been developed on new biomarkers to track the onset and development of disease (Naylor and Eastell 2012; Pisetsky et al. 2012; Rousseau and Garner 2012). Nevertheless, such imaging findings are poor to moderate predictors of disability; and biomarkers are still in their youth and are not yet being used reliably and widely in clinical settings.

The key feature determining disability and rehabilitation from MSDs among individuals is the presence of pain (Laisné et al. 2012). Once pain occurs as a result of MSDs, most likely it will occur again intermittently throughout the individual's lifetime. If pain lasts long enough and/or is perceived as strong enough it will result in disability. How pain is managed is therefore crucial as it ultimately determines the burden of MSDs to individuals, their families, and society. The ways in which pain affects how people feel are complex and remain undetermined; however, it appears that emotional processes (e.g. depression) may be involved in how pain is perceived and, therefore, its consequences. Cognitive

(e.g. increased attention to pain), behavioural (e.g. low levels of physical activity, limitation of adaptive pain-coping behaviour, and impairment of social support), and neurophysiological factors (e.g. enhanced central nervous system pain processing and impaired neuroendocrine function) seem to mediate the pathway from emotional disturbances to final outcomes (Edwards et al. 2011).

LBP, neck pain (NP), OA, osteoporosis, and RA are some of the most common conditions among MSDs causing the largest public health burden to society worldwide.

Low back pain

Definition of LBP

LBP is characterized as pain manifesting from the anatomical area between the 12th rib and the superior aspect of the thigh either with or without radiating leg pain (Krismer et al. 2007). LBP can result from several different causes. Non-specific LBP has received the most attention from the healthcare arena because it represents more than 80 per cent of the LBP cases seen in the healthcare setting. This type of LBP can be initially classified based on whether or not it presents with pain in one or both legs, and on pain duration.

Pathophysiology of LBP

The pathophysiology of LBP can generally be classified as either mechanical or non-mechanical in origin (Biyani and Andersson 2004). Mechanical LBP can be due to disc herniation, where the annulus fibrosis around the disc tears, allowing the disc nucleus to push against nearby nerve roots and cause pain. Another possible mechanical pathway for LBP that is commonly seen in ageing populations are arthritic spurs that impinge around adjacent nerve roots in the spinal canal igniting pain. As we age, bone remodelling can cause spurs to develop at the vertebral bodies and these spurs can directly compress these nerve roots and vascular structures leading to pain, inflammation, and secondary oedema. Non-mechanical LBP can be caused by neoplastic, infectious, inflammatory arthritis, or other diseases (e.g. Paget's disease, Scheuermann's disease, Basstrup's disease, etc.); however, they are not a focus of discussion in this chapter (see Jarvik and Deyo 2002).

Natural history of LBP

Most people will feel LBP at least once in their lives independently of the root causes, although only a proportion of them is likely to seek help from healthcare services (Balagué et al. 2012). Among individuals with non-specific LBP, the frequency and duration of pain can vary considerably, with some individuals reporting multiple periods of pain with interspersed periods of less severe or no pain. This period of pain could be brief, lasting a few days, or it could be longer lasting, over a few weeks or even months, that eventually leads to disability. If the pain lasts for a significantly extended period of time beyond the normal healing period of approximately 2 months, then a chronic pain syndrome could arise (Krismer et al. 2007). Studies have also shown that when pain radiates down one or both legs there is a strong association with more significant loss of function (Hoy et al. 2010).

While a great majority of adults will experience one episode of back pain during their life, many adults will also experience new episodes of back pain (Jeffries and Grimmer-Somers 2007). In

fact, recent studies have classified individuals who seek healthcare for back pain into four categories, including: those people with 'persistent mild' pain; those who start with mild pain, progressing quickly to 'recovering' with no pain; those with 'severe chronic' pain who have permanently high pain; and those with 'fluctuating' pain whose pain varied between mild and high levels (Dunn et al. 2006).

Risk factors for LBP

Risk factors for a new episode of LBP may include: poor general health, female gender, and body weight in women (Croft et al. 1999); genetics and age (incidence is higher in the third decade (Hoy et al. 2010)); occupational exposures and education (Hoy et al. 2010). Although by definition non-specific LBP has unknown causes, there are known associations between LBP and degeneration of the lumbar discs seen with clinical imaging. The scientific literature suggests that mechanical factors are associated with self-reported LBP; however, several meta-analyses and systematic reviews have suggested that mechanical factors such as awkward posture, manual material handling, pushing or pulling, and prolonged occupational sitting are not causal factors of LBP. Obesity and smoking may also play a role (Balagué et al. 2012). Genetic factors may also be implicated via disc narrowing effects on pain or via two genes (i.e. catechol-O-methyltransferase (*COMT*) and the μ -opioid receptor (*OPRM1*)) implicated in pain perception, signalling, psychological processing, and immunity. Interleukin-1 gene cluster polymorphisms are associated with modic changes and might have a pathogenic role. Genotype has also been reported to be associated with the outcome of surgery for degenerative disc disease (Balagué et al. 2012).

Treatment of LBP

In general, the recovery from acute LBP either with or without radiating pain down the legs has a favourable recovery profile. While certain interventions such as stress management, shoe inserts or insoles, back supports, ergonomics or back education, and reduced lifting programmes are not effective, exercise interventions seem to be the most effective in reducing LBP. For example, intervention studies have shown that when compared to individuals not randomized to the intervention group, those who receive specific training and advice on proper manual material handling either with or without the use of assistive devices, report less sick leave (Balagué et al. 2012).

Neck pain

Definition of NP

NP encompasses a broad range of different clinical presentations and has been defined as pain in the neck that lasts for at least 1 day either with or without radiating upper limb pain that is associated with activity limitations (Hoy et al. 2010). NP can result from different specific causes (e.g. trauma) or serious pathologies (e.g. inflammatory disorder, radiculopathy, or myelopathy), but in the majority of cases, as it was for LBP, NP is non-specific (Hoving et al. 2001).

The Bone and Joint Decade's Task Force on Neck Pain and Its Associated Disorders (Carroll et al. 2008) recommended classifying NP through the following scheme:

- ◆ Grade I NP: no signs or symptoms suggestive of major structural pathology and no or minor interference with activities of

daily living; will likely respond to minimal intervention such as reassurance and pain control; does not require intensive investigations or ongoing treatment.

- ◆ Grade II NP: no signs or symptoms of major structural pathology, but major interference with activities of daily living; requires pain relief and early activation/intervention aimed at preventing long-term disability.
- ◆ Grade III NP: no signs or symptoms of major structural pathology, but presence of neurological signs such as decreased deep tendon reflexes, weakness, and/or sensory deficits; might require investigation and, occasionally, more invasive treatments.
- ◆ Grade IV NP: signs or symptoms of major structural pathology, such as fracture, myelopathy, neoplasm, or systemic disease; this grade requires prompt investigation and treatment.

Pathophysiology of NP

In a large number of individuals, NP can be a result of either muscular or ligamentous factors related to posture, poor ergonomics, stress, and/or chronic muscle fatigue. Neck muscle pain can also develop secondarily as a consequence of postural adaptations to a primary source of pain in the shoulder or other upper extremity joints (Bogduk 2011). Individuals with degenerative arthritis in the upper cervical joints can present with severe NP that transmits down into the neck or to the back of the ear.

Natural history of NP

Similar to the low back, NP is first experienced in childhood or adolescence and can manifest several times over the life course. In fact, a large proportion of individuals with NP never really experience complete resolution of their pain. Recent research studies have shown that between 50 and 85 per cent of those who experience NP at some point in their life will report NP again 1–5 years later (Haldeman et al. 2010). This NP experience appears to be similar in the general population, workers, and among individuals who experience motor vehicle crashes (Haldeman et al. 2010).

The presentation of NP among individuals who seek healthcare can vary and includes concomitant pains such as headache, shoulder, upper limb, upper and/or lower back pain (Leaver et al. 2013). However, among individuals with non-specific NP, the origin of the pain and its progression can also vary. In addition, pain arising from anatomical regions other than the neck can be explained as referred pain from innervated cervical spine structures, or as other regional conditions coexisting with NP, or as the presence of a generalized, widespread pain syndrome involving NP. Nonetheless, NP can be a complex health condition that is difficult to treat and contributes significantly to the burden of MSDs (Leaver et al. 2013).

Several factors can affect the course of NP. For example, younger age is associated with a better prognosis, whereas poor health and prior NP episodes are associated with a poorer prognosis. Poorer prognosis is also associated with poor psychological health, worrying, and becoming angry or frustrated in response to NP. Greater optimism, a coping style that involved self-assurance, and having less need to socialize, are all associated with better prognosis. Specific workplace or physical job demands are not linked with recovery from NP (Haldeman et al. 2008).

Risk factors for NP

Poor general health, smoking, higher pain, and lower Short-Form Health Survey (SF-12) mental component scores have been reported to be independently associated with higher-level disability resulting from NP (Leaver et al. 2013). Several epidemiological studies suggest that risk factors for NP have a multifactorial aetiology. For example, non-modifiable risk factors for NP include age, gender, and genetics; however, there is no evidence that common degenerative changes in the cervical spine are risk factors for NP. Research studies have also documented that additional modifiable factors for NP include smoking, exposure to environmental tobacco, and physical activity participation. Occupational health studies have also documented that high quantitative job demands, low workplace social support, sedentary work position, repetitive work, and precision work have been associated with increased risk of NP (Haldeman et al. 2008).

Treatment of NP

Generalized NP can be treated conservatively with the use of over-the-counter pain medications, ice, heat and massage, and strengthening and/or stretching exercises at home. Current strategies suggest that if the pain persists after a few weeks of conservative treatment, then further evaluation is warranted (Haldeman et al. 2010). There is a dearth of high-quality evidence elucidating the best specific treatment for NP in general. For instance, there are many reviews as there are controlled trials of therapies for NP; yet for many interventions, there is no concordance in the conclusions drawn by reviewers. Few studies have been conducted on the long-term effects of treatments for NP. As an illustration, a study conducted by Haldeman et al. (2008) suggested that compared to quality of life years with the use of standard non-steroidal anti-inflammatory drugs (NSAIDs), Cox-2 NSAIDs, exercise, manipulation, and mobilization among adults with NP, active treatments are not significantly superior to any other treatment option in the short or long term even after controlling for adverse event risks, treatment effectiveness, and patient preferences for health outcomes in their models (Linton and van Tulder 2001; Haldeman et al. 2008).

Osteoarthritis

Definition of OA

OA is a degenerative disorder of the joints that can also be termed degenerative joint disease, degenerative arthritis or osteoarthrosis. It is comprised of a group of joint conditions that involve degradation of joint tissues, including the articular cartilage and subchondral bone. Joints of the hip and knee are most frequently affected, but the joints of the hand, spine, and feet are also typically affected. Individuals with these conditions report feeling specific pain, tenderness, stiffness, and locking around the joint. Among people with chronic joint degeneration one may see muscle shrinkage and ligament loosening around the joint. Current classification schemes for OA include documentation of loss of cartilage, subchondral sclerosis, subchondral cyst formation and osteophytes on radiological imaging, and self-reported joint pain (Fransen et al. 2011).

Pathophysiology of OA

OA is said to be primary if it originated without a known cause (Punzi et al. 2010). However, OA can also be secondary to

other diseases such as congenital joint disorders and diabetes. Traditionally, OA was thought to affect primarily the articular cartilage of synovial joints; however, pathophysiologic changes are also known to occur in the synovial fluid, as well as in the underlying bone structures, the overlying joint capsule, and other joint tissues (Punzi et al. 2010). During the early phases of OA, swelling of the cartilage usually occurs, because of the increased production of proteoglycans that reflects an effort by the cartilage's cellular structures to repair cartilage damage. This phase may last for several years or decades and is characterized by intense repair of the articular cartilage. As OA progresses further, however, the cartilage eventually begins to soften and lose elasticity and thereby further compromises joint surface integrity. At the microscopic level, flaking and fibrillations develop along the normally smooth articular cartilage on the surface of an osteoarthritic joint. In the long run, this loss of cartilage results in loss of joint space (Punzi et al. 2010).

Natural history of OA

OA is a joint condition that involves a slow, progressive degeneration of the joint and is the most common type of all arthritis conditions. We now know that OA develops as a result of articular cartilage damage that can be triggered by a complex interplay of genetic, metabolic, biochemical, and biomechanical factors with secondary involvement of the inflammation pathway. The overall natural process involves interactive degradation and repair processes of cartilage, bone, and synovium. Of all the cells involved in the aetiology and pathogenesis of OA, chondrocytes play a large role. Studies on animals and humans suggest that these cells exhibit numerous metabolic dysfunctions leading to OA. This pathology more than any other disease pathology can result in difficulties in daily activities such as walking, stair climbing, and other lower-extremity tasks (Gabriel and Michaud 2009).

Risk factors for OA

OA is said to be a primary disorder if it originates without a known cause, although evidence suggests that risk factors such as genetic predisposition, age, obesity, female sex, greater bone density, joint laxity, and excessive mechanical loading are associated with its aetiology (Punzi et al. 2010). Recent evidence from North American and European cohorts suggest that obesity or heavy occupational physical activity are risk factors for symptomatic knee and hip OA (Gabriel and Michaud 2009; Fransen et al. 2011). In addition, several other international studies have documented that a history of joint injury, frequent stair climbing, or frequent lifting of heavy weights is significantly associated with hip OA where the strongest association was among individuals with a history of joint injury. In a case-control study in Japan, there was an association with occupational lifting but no association with obesity (Fransen et al. 2011). In another study, OA has been associated with high obesity levels and cardiovascular disease which can cause synergistic effects (Punzi et al. 2010).

Treatment of OA

While there is no known cure for OA, certain treatments can help to reduce pain and maintain joint movement. Treatment generally includes exercise, lifestyle modification (e.g. diet), and pain relievers. If the condition is severe, joint replacement surgery is typically recommended. While specific medications designed to reduce pain (e.g. acetaminophen and opioid analgesics) are helpful, they

do not have an effect on joint inflammation as do NSAIDs. In more severe cases of OA, there are two types of injections that have shown moderate evidence for pain improvement: steroid (i.e. glucocorticoid) injections and injections of a liquid known as hyaluronate, designed to mimic the natural fluid found in joint space (Iagnocco and Naredo 2012). Once these conservative and minimally invasive approaches have been exhausted, a surgical approach to rehabilitating the OA joint may be needed (Iagnocco and Naredo 2012).

Osteoporosis

Definition of osteoporosis

Osteoporosis is classified as either primary or secondary depending on what is causing the disease. The primary form of osteoporosis is a metabolic bone disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and increased fracture risk (Riis 1993). Secondary osteoporosis can result from a variety of the chronic conditions that significantly contribute to bone mineral loss, or it can result from the effects of medications and nutritional deficiencies. The WHO defines osteoporosis using bone density, that is, a bone density score that is 2.5 standard deviations (SDs) or more below the young adult mean value (T-score < -2.5). However, individuals with bone density between scores 1 and 2.5 SDs below average (T-score -1 to -2.5) are said to have osteopenia (Kanis et al. 1994). In the case of the spine, decreased bone density imparts increased risk for bone fracture; for every 1 SD decrease in bone density of the spine there is an increased risk for new vertebral fractures by factor of 2.0–2.4 (Wasnich 1993).

Pathophysiology of osteoporosis

Changes in bone mass acquisition during human growth and development and accelerated bone loss in the period after peak bone mass are both leading mechanisms for the development of osteoporosis. Studies have shown that both of these mechanisms are influenced by environmental and genetic factors (Iagnocco and Naredo 2012). In postmenopausal women, studies have attributed about two-thirds of the risk of fracture to be related to the premenopausal peak bone mass (Farmer et al. 1984). In twin and mother–daughter dyad studies, about 40–80 per cent of the variability observed in bone mass can be attributed to genetic factors. In fact, biological studies have suggested that genes regulating oestrogen receptors, transforming growth factor- β , and apolipoprotein E and collagen, influence the development of osteoporosis. Conversely, bone loss is more strongly influenced by individual-level factors such as nutritional, behavioural, and pharmacological factors yet is still associated to a lesser degree with oestrogen genetic factors (Ronis et al. 2011).

Natural history of osteoporosis

Among all metabolic bone diseases, osteoporosis is the most prevalent. In fact, in the United States alone, approximately 54 per cent of postmenopausal white women have osteopenia and 30 per cent have osteoporosis. Osteoporosis is a complex and dynamic disease of bone where there is an asymptomatic reduction in the quantity of bone mass per unit volume. When the bone mass reaches a very low threshold, the structural integrity and mechanical support provided by the bone fails, leading to fractures. The overall natural process of this disease involves a dysregulation of the homeostatic

processes between osteoclastic (bone destruction) and osteoblastic (bone growth) activity. If sufficient remodelling in one direction occurs (i.e. more bone destruction than growth), the bone becomes weakened and this could lead to fractures (Hoy et al. 2010, Huizinga and Pincus 2010).

Risk factors for osteoporosis

There are several well-known modifiable and non-modifiable risk factors for osteoporosis. Recent epidemiological studies in the United States suggest that men and non-white women at risk add approximately 30–54 million affected people. These bone diseases place individuals at higher risk for osteoporotic fractures (Hoy et al. 2010). Racial and ethnic differences in the prevalence of osteoporosis and osteoporotic fractures have been well documented. For example, among black people, hip fracture is considerably more prevalent than among white people primarily due to differences in higher peak bone mass and slower postmenopausal bone loss noted in African American women (ILO 2000). Some studies have also noted that women of Asian descent have lower bone mineral density than white women (Jarvik and Deyo 2002). In terms of age, studies have shown that decreased bone mineral density and osteoporotic fracture rates increase throughout the life course. For example, the incidence or number of new cases of hip fractures begins to increase during the seventh decade of life, vertebral fractures during the sixth decade, and wrist fractures during the fifth decade. While hip and vertebral fractures have been associated with increased mortality rates, the loss of autonomy and lower health-related quality of life remain the largest public health burden of this disease. Similarly, men also suffer from osteoporosis yet not at the same rate as women. For example the increased incidence of hip fracture in men occurs about 5–10 years later than in women (Isaacs 2010, Kanis et al. 1994). In summary, non-modifiable risk factors include age, body size, race, and family history (Drake et al. 2012; Wright and Saag 2012) while modifiable risk factors include sex hormone deficiencies, diet, certain medical conditions (e.g. anorexia nervosa) and medications, lack of physical activity, heavy alcohol consumption, and smoking (Wright and Saag 2012).

Treatment of osteoporosis

The treatment plan for osteoporosis is often multifaceted, including pharmacological and behavioural interventions to reduce risk of fracture and improve bone mineralization. For example, a treatment plan could include activities and exercise, improving nutrition, and educational training on the prevention of falls. Pharmacological interventions often complement these approaches and include drugs that modify bone reorganization, increase bone density, and subsequently reduce fracture risk. Mineral and vitamin supplementation is also paramount and includes the combined use of calcium and vitamin D (Drake et al. 2012).

Rheumatoid arthritis

Definition of RA

RA is a disease characterized by chronic inflammation of the joints; however, adjacent tissues and other body organs (i.e. such as the skin, heart, lungs, and eyes) can also be affected. In this condition, the body's immune system has turned on itself and attacks the tissues and structures within the joints. While any joint can be affected by RA, the hands and feet are most commonly affected

and have the greatest potential to lead to joint destruction and functional disability (Huizinga and Pincus 2010).

Pathophysiology of RA

While the direct aetiology of RA is not well understood, several risk factors have been associated with the onset of an immune system reaction, including a joint infection, trauma, and tobacco smoke. These immune system triggers cause the tissues within the joint to enlarge and cause inflammation, particularly among individuals who have a genetic disposition for immune sensitivity. Ultimately the chronic inflammation in the joint leads to the destruction of various joint tissues, including cartilage.

Natural history of RA

The overall world prevalence of RA is approximately 1 per cent. In the United States, for example, the prevalence of RA has been documented to be approximately 0.6 per cent (1.3 million adults) of the population. Epidemiological studies have also documented geographic variations in the prevalence of RA where it is found highest among Pima (5.3 per cent) and Chippewa Indians (6.8 per cent), and lowest among individuals from Japan and China (0.2–0.3 per cent) (Helmick et al. 2008). These geographic variations in the prevalence of the disease further suggest that either a genetic or environmental component may be present (Silman and Pearson 2002). Recent population-based estimates suggest that approximately one-third of individuals with RA become work-disabled within 2 years of disease onset, and approximately 50 per cent are work-disabled after 10 years (Combe 2009; Isaccs 2010). Part of this disability and decrease in health-related quality of life is due to the physical, emotional, and social impact of the disease. While physician rating of patient pain is generally lower than pain self-reported by the patient, disease severity has been associated with the degree of pain experienced by the patient as well as their physical functioning.

Risk factors for RA

Research studies have identified both modifiable and non-modifiable risk factors that contribute to the development of RA. In fact, a large proportion of RA cases are believed to arise from the interaction between genetic (i.e. non-modifiable) and environmental (i.e. modifiable) exposures. For example, the number of new RA cases is typically two to three times higher in women than men while the onset of RA is highest among those individuals in their 60s for both men and woman (Silman and Pearson 2002). There are several modifiable risk factors that have been studied in association with RA including cigarette use, nutritional/dietary factors, infectious agents, and reproductive hormonal exposures (Pincus and Callahan 1993). Of these factors, tobacco exposure has been shown in the epidemiological literature to be the strongest and most consistent in terms of being associated with RA, particularly among people who have specific immune markers in the blood (e.g. test positive for anti-citrullinated protein/peptide antibodies) (Scott et al. 2010). Other studies have documented mixed evidence of an association between the use of oral contraceptives and a risk of RA (Brennan et al. 1997).

Treatment of RA

Treatment options for RA can vary from the newest RA drugs to inclusion of exercise and NSAIDs as well as individualized care and management tips. There are two types of drugs used

in treating RA, classified as first- and second-line medications. The first-line drugs include agents such as aspirin and steroids that are commonly used to reduce the person's pain and inflammation. Second-line drugs are slow acting and include the disease-modifying antirheumatic drugs such as methotrexate (i.e. Rheumatrex® and Trexall®), and hydroxychloroquine (i.e. Plaquenil®) that thwart progressive joint disease and support remission. RA usually requires lifelong treatment, including medications, physical therapy, exercise, education, and surgical intervention depending on the disease severity (Ibrahim et al. 2012).

The scope of the problem

Hundreds of millions of people suffer from MSDs worldwide. The independence and autonomy of people to perform daily normal activities is affected by MSDs. Furthermore, epidemiological studies have documented how MSDs can affect a person's capacity to work and live independently. In fact, among individuals suffering from MSDs, the value in life that was going to be created by these sufferers can now be considered lost to society. Immeasurable suffering accompanies people with MSDs and their families. Families and society (e.g. government, industry) often contribute to social welfare and healthcare programmes that subsidize health services (Fransen et al. 2011).

Understanding and quantifying the magnitude of problem that MSDs bring to society is a difficult task (Caban-Martinez et al. 2011). Most cost estimations include only health expenditures and are available only for selected diseases and for some countries. On the other hand, measures based on disease occurrence (prevalence rates and proportion incidence) can offer a comprehensive overview of the problem in different geographical areas of the world, but not without methodological difficulties (e.g. as MSDs have a slow onset, it is frequently hard to identify the moment when the disease starts). The Global Burden of Disease (GBD) report, which uses a more elaborate measure (disability-adjusted life years (DALYs)), has recently become available. In the following subsections we present an overview of the MSD burden based on disease cost, occurrence, and years of life lost.

A few important messages can be highlighted from the information available: (1) MSDs occur very frequently, (2) MSDs are expensive, (3) the extent of the problem of MSDs is increasing over time, and (4) there are important geographical differences in the geographical distribution of MSDs.

MSDs occur very frequently

The GBD study estimated that 1700 million people suffered from MSDs in the year 2010 (Table 8.9.1). Years lived with disability (YLDs) of MSDs are not declining (Vos et al. 2012). To understand these numbers it is important to consider a few key methodological characteristics of these estimations. First and most importantly, not all MSDs were included in the study that produced these global estimations¹; and important conditions that do fall in the MSD diagnosis categories as defined in the ICD-10 were not counted as MSDs, which highlights the fact that more people can suffer from MSDs worldwide.

In spite of the great variability found in the literature regarding case definitions (e.g. case definitions for OA can vary depending on diagnosis criteria: radiographic, symptomatic, or

Table 8.9.1 Point prevalence (P; in thousands) and prevalence rate of major musculoskeletal diseases in year 2010

MSD type	Total		Males		Females	
	P	%	P	%	P	%
Low back pain ^a	632,045	9.17	334,793	9.64	287,252	8.70
Neck pain	332,049	4.82	135,134	3.89	196,915	5.77
Knee osteoarthritis	250,785	3.64	88,885	2.56	161,900	4.74
Other MSDs	560,978	8.14	26,2779	7.56	298,199	8.73

^a Activity-limiting low back pain (\pm pain referred into one or both lower limbs) that lasts for at least 1 day (Hoy et al., 2012).

Reprinted from *The Lancet*, Volume 380, Issue 9859, Vos T. et al., Years lived with disability (YLDs) for 1160 sequelae of 289 diseases and injuries 1990–2010: a systematic analysis for the Global Burden of Disease Study 2010, pp. 2163–96, Copyright © 2012, with permission from Elsevier, <http://www.sciencedirect.com/science/journal/01406736>.

clinical (Gabriel and Michaud 2009)), and the notable difference in information availability for different populations, the GBD study made an effort to produce case definitions that were consistent and to include some description of the impact of the condition on daily activities and loss of function (Woolf et al. 2010).

MSDs are expensive

In 2009, the world spent a total of US\$5.97 trillion in health-related expenses (WHO 2012). This figure includes government expenditures and out-of-pocket expenditures in health. A large part of this cost is attributable to MSDs where among developed nations they are responsible for approximately 25 per cent of total expenses due to illness (Walsh et al. 2008). In addition, approximately 20 per cent of regular primary care visits in the vast majority of countries is due to MSDs (Walsh et al. 2008). The pain experienced by individuals with MSDs is one of the most common reasons for self-medication and for visits to a primary care setting. Among countries with ready access to medical care, MSDs account for a considerable number of healthcare visits and expenditures (Murray et al. 2012).

Most of the data available in terms of monetary expenditure on healthcare is representative of specific geographical areas and specific MSD, most frequently in developed countries. In the State of Victoria, Canada, for example, MSDs were the most frequent reason for outpatient visits to the medical centre (11.6 per cent of the total) between the years 1997 and 2000. Also, among 26 medical specialties, MSDs had the sixth highest number of inpatient episodes (6.2 per cent in years 2000/2001). In terms of cost, MSDs rank fifth in the number of bed-days away from work during the period 1997 to 2001 (Osborne et al. 2007).

These expenditures are not unique to Canada. An economic study on LBP in the United Kingdom estimated that the direct costs of LBP were £1.6 billion in 1998. When factoring the indirect costs associated with LBP, countries such as Sweden (costs per capita: US\$24 direct costs versus US\$266 indirect costs, 8 per cent versus 92 per cent) and the Netherlands (US\$24 direct versus US\$299 indirect, 7 per cent versus 93 per cent) had direct costs lower than indirect expenditures spent in the UK alone. In the United States, data from the 1988 National Health Interview Survey documented that general LBP accounted for 149 million lost work days annually while work-related LBP accounted for 102 million work days lost. In total, all cases of LBP were estimated to cost about US\$1230 on average for men and US \$773 on

average for women with an annual productivity loss of \$28 billion (Krismer et al. 2007).

The burden of MSDs is growing

In 2010, the burden of MSDs was quantified and updated using the DALY metric. This metric aims to quantify how many years are lost due to disability (YLDs) and due to mortality (years of life lost (YLLs)) for a list of 291 conditions. In simple terms, for example, if a person loses part of her capacity to perform daily activities due to a particular condition (disability weight of the condition), that person loses proportionally part of the years that she was going to live until her expected age of death. The sum of these two losses are the DALYs. For each condition 1160 sequelae were identified. For example, for the condition 'low back pain', four sequelae resulting from combining acute or subacute versus chronic pain, and pain in one or both legs versus without this pain were identified (Hoy et al. 2010). YLDs are computed as the prevalence of a sequela multiplied by the disability weight for that sequel. The YLDs arising from a disease or injury are the sum of the YLDs for each of the sequelae associated with that disease. In the study the prevalence of sequelae was estimated with uncertainty for 20 age groups, two sexes, and 21 regions of the world. The value of these estimations is based on the fact that an attempt was made to achieve comparable figures for different geographical areas for two moments in time, in the years 1990 and 2010.

A few methodological aspects need to be highlighted in order to understand DALYs: the YLLs due to mortality are generally low due to MSDs. Part of this is due to the chronic nature of these conditions, which means that their effect is exerted through the loss of quality of life rather than to the loss of years of life. However, there are exceptions. For example, the death rate is increased for all osteoporotic fractures; however, the death will not be attributed to the underlying osteoporosis, it will instead be attributed to the injury. We also see this misclassification in other MSDs such as systemic vasculitis and untreated RA, where the death certificate will likely state that the death was due to end-organ failure or other co-morbidity. As a consequence the metric does not fully capture the premature loss of life due to the individual living with the MSD. For conditions with low mortality rates such as OA, there might actually be a greater burden of death due to the condition (Woolf et al. 2010). In the case of morbidity, it is possible to estimate the YLL due to living with MSDs. It is possible to consider measuring the health state of the individual by using a set of

health domains, such as overall well-being, general health, physical health, social health, mental health, and barriers to participation. In the GBD study, health loss associated with individual loss of physical and emotional function was measured rather than general welfare loss and loss of participation.

The general distribution of the burden of disease has shifted from a previously greater burden of communicable, maternal, and neonatal causes to non-communicable diseases including MSDs. In 1990, approximately 47 per cent of DALYs were caused by communicable, maternal, and neonatal causes, 43 per cent from non-communicable diseases, and 10 per cent from injuries as compared to estimates in 2010 that had shifted to 35 per cent, 54 per cent, and 11 per cent, respectively (Murray et al. 2012). In absolute terms, worldwide the DALYs due to MSDs grew from 116.6 million (116,553 thousand (88,683–147,285)) in 1990 to 169.6 million (169,621 thousand (129,768–212,730)) in 2010 (45 per cent increase); or in relative terms from 2.2 million (2198 thousand (1673–2778)) to 2.5 million (2462 thousand (1883–3088)) per 100,000 thousand people (12 per cent increase) (Table 8.9.2). These conditions would be responsible for 6.8 per cent of the DALYs, which is a much larger share compared to the 2 per cent estimated in year 2004 (Murray et al. 2012); and is particularly high in the regions with an advanced demographic and epidemiological transition, where MSDs account for 13 per cent of the DALYs.

From 1990 to 2010, the proportions of specific disease conditions in the MSDs have not changed significantly; however, LBP (49 per cent), NP (20 per cent), and OA (10 per cent) all share the largest proportion of the pie among all MSDs. Population-based survey data suggests that this observed growth in MSDs might not be due to the growth in the population alone given the relative-to-population increase of 26.5 per cent.

MSD is a larger burden for people older than 39 years old. However, it is clear that MSDs for males start being an important issue (considering all DALYs) as early as 10–14 years old in

relation to other conditions at that age range, and this is pretty much maintained until the age of death; MSDs become one of the most important types of conditions in the age range from 35 to 50 years. For women, MSDs start being important at age 14 as well. However, as a proportion of all disease that women can suffer, MSDs are more important; and the age range when MSDs are most important is from 40 to 55 years (Murray et al. 2012). Considering only YLDs, for both males and females it appears that MSDs start being an important issue at the age of 10 but peak at the ages between 45 and 64 (Vos et al. 2012).

Through a geographical lens, it is clear that most world regions will have to prioritize MSDs, which went from being ranked 11th among all assessed conditions in 1990 to being ranked sixth in 2010. This is especially true for conditions such as LBP which is a problem pretty much everywhere in the world (Fig. 8.9.1). Considering only conditions capable of resulting in disability (as opposed to mortality), LBP was first in priority in the years 1990 and 2010; NP was fourth in priority in both 1990 and 2010; other MSDs went from fifth priority to sixth priority between the years 1990 and 2010. Lastly, OA went from 15th to 11th priority (Vos et al. 2012). In analysing these figures, it is important to consider that the hip and knee account for the greatest proportion of disability attributed to OA (Fransen et al. 2011).

Determinants of musculoskeletal disorders

Four risk factors can be considered major drivers of MSD occurrence worldwide: obesity (Lim et al. 2012), ageing, and the increase in trauma (particularly via road traffic collisions) (Walsh et al. 2008) and repeated mechanical loading (particularly via working conditions) (Lim et al. 2012). At another level of causation, behavioural changes related to diet and physical activity may be driving observed changes in obesity. Major determinants of these

Table 8.9.2 DALYs related to major MSDs in both sexes by age groups

Cause	50–54 years	55–59 years	60–64 years	65–69 years	70–74 years	75–79 years	80+ years
MSDs	15,257.4 (11,840–18,871.8)	14,581.2 (11,434–17,934.2)	12,160.5 (9,634.2–14,908.8)	9,695.7 (7,740.5–11,859.0)	8,292.9 (6,568.1–10,139.3)	5,685.5 (4,432.7–7,000.4)	6,115.7 (4,791.0–7,504.6)

behavioural changes include technological development, income increase, globalization, growth of mass media, and urbanization (Fig. 8.9.2).

Paradoxically, technological improvements have resulted in different consequences. On the one hand, medical advances and prevention of infant mortality (Anderson and Arias 2003) have contributed to the increase in human life expectancy (Olshansky et al. 2005) and to the ageing of the world's populations and, therefore, to the occurrence of MSDs. Also, technological advances have made possible the reduction of physical demands (Popkin et al. 1989), at least for a part of the population, which may have also contributed to obesity and therefore to the occurrence of MSDs. Lastly, the lack of permeation of such advances in many industries contributes to the existence of large, sudden physical demands or permanent low demands that are capable of promoting the occurrence of MSDs.

Other related factors include: (1) worldwide shifts in the trade of technology innovations that affect energy expenditures during leisure, transportation, and work; (2) globalization of modern food processing, marketing, and distribution techniques (most frequently linked with Westernization of the world's diet); (3) vast expansion of the global mass media; and (4) other changes that constitute the rubric of the effects resulting from an increased opening up of the world economy (Popkin et al. 1989).

Ageing

The world population is ageing. The median of the world population has gone from 23.9 years in 1950 to 29.2 years in 2010 (Fig. 8.9.3). The population above 60 worldwide has gone from roughly 204 million (8.1 per cent of the total population) in 1950 to 865 million (12.4 per cent of the total population) in 2010; and the population above 80 years old went from roughly 15 million (0.6 per cent of the total population) to roughly 210 million in 2010 (3 per cent of the total population) (United Nations 2012).

The current median age of the population in Europe, North America, and Oceania are much above the average. The growing trend in Europe is especially concerning as is the current trend in Asia, Latin America, and the Caribbean. Many countries in Asia are ageing rapidly. The number of people aged over 65 has doubled from 6.8 per cent in 2008 to 16.2 per cent in 2004. It is expected that from 2008 to 2040, the proportion of people over 65 will grow by 316 per cent in Singapore, 274 per cent in India, 269 per cent in Malaysia, 261 per cent in Bangladesh, and 256 per cent in the Philippines. In 2008, Japan had the oldest population, and in absolute terms, China and India have the largest number of people over 65 (approximately 106 and 60 million) (Fransen et al. 2011).

Obesity

A major worldwide public health concern is the increasing growth of overweight and obese individuals in both developed

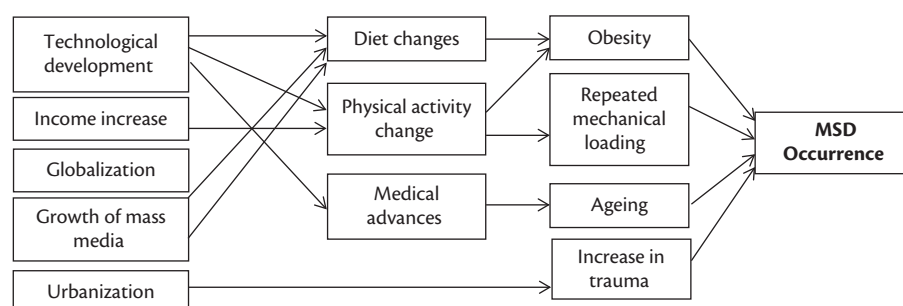

Fig. 8.9.2 Conceptual model relating the major determinants of musculoskeletal disorders.

Fig. 8.9.3 Median age of the world population in the last 50 years.

Adapted from United Nations (UN), Population Estimates and Projection Section, United Nations Department of Economic and Social Affairs, Copyright © 2012, available from: <http://esa.un.org/wpp/Excel-Data/population.htm>.

and now developing countries. Several epidemiological studies have correlated the burden of overweight and obesity to MSDs and other health outcomes. This phenomenon is of great public health concern given that between 1980 and 2008, the mean body mass index (BMI; a proxy measurement for overweight and obese levels) worldwide increased by 0.4 kg/m² per decade for men and 0.5 kg/m² per decade for women. Gender and geographic differences in BMI status have been changing over the years. For example, male and female BMIs in 2008 were highest in specific Oceania countries, reaching 33.9 kg/m² for men and 35.0 kg/m² for women in Nauru. Female BMI was lowest in Bangladesh (20.5 kg/m²) and male BMI in the Democratic Republic of the Congo 19.9 kg/m², with BMI less than 21.5 kg/m² for both sexes in a few countries in sub-Saharan Africa, and east, south, and South East Asia. The United States had the highest BMI of high-income countries. In 2008, an estimated 1.46 billion adults worldwide had a BMI of 25 kg/m² or greater; of these, 205 million men and 297 million women were obese (Finucane et al. 2011).

Multiple factors are contributing to this trend of increasing overweight and obesity in developing countries, and are likely to have a major impact on MSDs in the future. For example, several low-income countries such as Mexico, Egypt, and South Africa have equally high levels of obesity among women as compared to higher-income countries. China also has obesity rates of 20 per cent for women and men (Popkin et al. 1989). In Asia, the population is also getting obese (Fransen et al. 2011). From 1992 to 2000, using nationally representative data for women aged 20–49 years in 36 countries, the proportion of overweight plus obese individuals exceeded underweight in most countries (Popkin et al. 1989). Small urban–rural differences in overweight, high absolute levels of overweight plus obesity, and very high ratios of overweight plus obesity to underweight have also been documented among countries with a high income and urbanization. There are even high levels of overweight individuals in rural areas of many poor countries where underweight individuals remain a public health concern. Most importantly the rates of change in the prevalence of overweight and obesity in these countries are growing. A large number of lower- and

middle-income countries such as Mexico, Thailand, China, and Indonesia are experiencing an annual increase in overweight and obesity of 1 per cent (Popkin 2006). Even more concerning is the fact that the obesity problem in children matches the adult obesity, with the concomitant problems related to diabetes (Popkin et al. 1989).

Overweight and obesity can also be directly explained by the level of physical activity and diet. Although there is significant variability between countries, it is true that around the world, diet and nutritional food consumption has become increasingly energy-dense and sweeter; and that processed foods are replacing foods that are high in fibre (Popkin 2006). On the other hand, the desire to reduce physical demands has always being an objective. In the advent of the information age, where more modern technologies are used in the workplace, in the shopping arena, and at home, there is likely to be decreased levels of physical activity. The picture of overall shifts in activity, their causes, and their consequences are still incomplete. Since the beginning of time, humans have made efforts to reduce physical effort in the home and at work. In addition, the growing demand for goods that are tasteful including portions higher in fat and sugars has been growing (Popkin et al. 1989). For example, the total daily calories ingested by US children aged 2–19 years increased on average from 2065 calories in the years 2003–2004 to 2952 in the years 2005–2008; while in adults there was a slight reduction from 2170 to 2106 for the same periods (Economic Research Service 2012).

The Economic Research Service (ERS) has conducted a series of studies that have interesting conclusions about the factors that influence diet decisions. Demographic factors (i.e. lower income, younger age, and lower formal education), household characteristics (single head of the household, working parents), and acculturation (e.g. acculturated Hispanics), and misperceptions about quality of food at home, are related to lower-quality diets or bad habits regarding their diets (skipping meals, eating away from home) (ERS 2012).

The ERS found that habits such as having food away from home plays an increasing role in Americans' diets, usually with negative effects on diet quality (Guthrie et al. 2002).

Future directions

By now it should be clear that there are societal determinants of MSDs which act through several different complex pathways that give way to a significant increase in MSD occurrence, with important effects on human development and quality of life. To tackle such a complex problem, different strategies are required at different levels.

Policy level

Two actions that are non-specific to MSDs but are the platform for the health of the population are required: redressing general social inequalities, including in education, employment, housing, and food; and improving the health financing system. Such actions are typically in the range of action of governments and the platform over which other actions are built. No health system alone will be able to address health inequalities if these factors are not addressed. According to the International Labour Organization (ILO), social security benefits that include cover for lost wages in the event of illness are available to only one in five adults worldwide, and more than half of the world population lacks any form of social protection (ILO 1999, 2000). For example, approximately 5–10 per cent of adults in sub-Saharan Africa and Southern Asia as compared to 20–60 per cent of adults in middle-income countries have social security coverage. There has never been a time with as great a need for universal health coverage and strategies to finance it. Recommendations have been given by the WHO. Country governments need to make sure that if people pay at the entry level of health services, those payments should correspond to their capacity of payment on a sliding scale. They also need to improve access to and utilization of primary preventive services for the poor, despite the challenges of implementing such services in low-resource and economically constrained countries (WHO 2010b).

Efforts to finance these types of systems should include special attention to the need to better distribute available resources. Among Organisation for Economic Cooperation and Development (OECD) countries there is a known 20/80 syndrome in which they spend over 80 per cent of the world's resources on health yet make up less than 20 per cent of the world's total population. While only 6.5 per cent of the African and 3.7 per cent of South East Asian regions' gross domestic product is spent on healthcare, OECD countries spend a much larger proportion on health (12.4 per cent). Low-income countries with annual per capita income of less than US\$1005 relied most heavily on out-of-pocket payments to finance healthcare. In these countries, the share of out-of-pocket payment in total health expenditure measured in US\$ terms was 50 per cent compared to only 13 per cent in countries with incomes higher than US\$12,276 per capita (WHO 2010b).

Other important actions that are specific to MSDs at the policy level are the creation and awareness of the scope of the MSD problem and investing in MSD research. Creating awareness is required so that action is started. Awareness moves political willingness. The recent GBD study has placed MSDs as the sixth priority worldwide among all 291 selected conditions assessed in this study. In some areas, as was already shown, MSDs are the top priority in terms of the burden of this type of condition (Vos et al. 2012). Nevertheless, the task persists; the information needs to reach and be understood by policymakers to prompt action. Efforts by the Bone and Joint Decade, a global alliance for

musculoskeletal health, have focused on raising this awareness of the burden of musculoskeletal conditions by developing sustainable networks and improving access to cost-effective prevention and treatment (Global Alliance for Musculoskeletal Health 2014).

Healthcare systems are now confronted with the growing costs and increased prevalence of MSDs that will require a coherent policy for dealing with MSDs. Identifying and prioritizing the research efforts on the most effective and affordable strategies for low-resource countries to deal with these conditions is paramount (Murray et al. 2012). The revealed utmost importance of MSDs should have consequences regarding the health system's capital investments. As the expected future burden of MSDs grows, investment efforts into these cost-effective strategies will need to spread over a long-term 10-year outlook. In addition, training and educational efforts for the existing and upcoming healthcare workforce is urgently needed to adequately address the large group of individuals that will be afflicted with MSDs. Innovation in health professional education should include MSDs on a region-by-region basis, so that trends in demographic and epidemiological change are identified fast enough that a forward looking assessment of the burden can be incorporated (Murray et al. 2012).

Research in this area should follow the framework that is being proposed here. There are needs both at the policy level and at the practice level. At the policy level, there are important unresolved questions about what policies could help prevent MSDs and improve access to healthcare. At the practice level, there are needs specifically regarding best clinical practices and new treatments. An important area of research priority includes assessing the impact of modifiable risk factors through innovative treatment approaches. Public policy that addresses these risk factors may help to significantly reduce the public health burden and cost of MSDs (Haldeman et al. 2008).

Research on the specific risk factors that should be targeted in specific populations is still pending. For example, there is a dearth of epidemiological research from low- and middle-income countries in the Asian region on MSDs. Due to significant demographic and environmental differences influencing the onset and progression of various MSDs in these regions, it becomes challenging to reasonably extrapolate some of the risk factor finding from high-income countries to low- and middle-income countries. In developing countries, trends in obesity, the burden of heavy physical labour, diminished access to healthcare variations in the approach to pain treatment, and linguistic variation all contribute to differences in reported and treated MSDs (Fransen et al. 2011). Nonetheless, these observations could be lower or higher estimates of the true value, given the general lack of epidemiological data in these developing countries that could support the development of better policy (Gabriel and Michaud 2009).

Practice level

While research progresses, much is already known on what to do and it should be put into practice. We already know what the major modifiable risk factors for MSDs are and the ways to improve access to healthcare (Fig. 8.9.4). While they may require adjustments to be applied in specific contexts, the basic understanding of the problem and potential ways to tackle it have already been proposed.

For example, in the case of LBP treatment, there are several new scientific and clinical investigations underway to examine

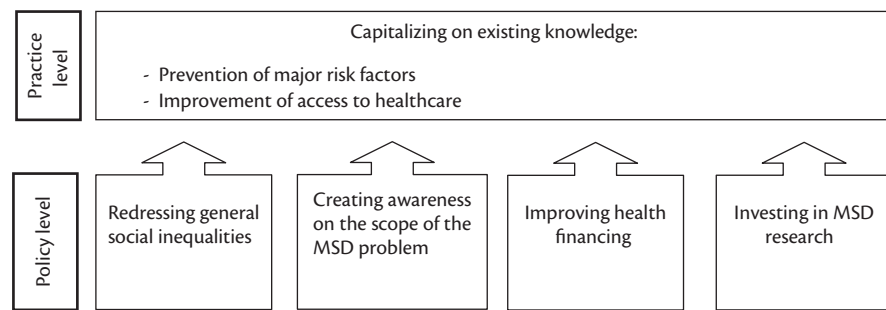

Fig. 8.9.4 Conceptual model for practice and policy levels addressing musculoskeletal disorders.

innovative technologies, new drugs, and strategic management approaches for individuals with LBP. The healthcare community should be encouraged by the fact that we already know so much about the challenges of LBP that are affected by a host of genetic, physical, psychological, environmental, cultural, and societal factors (Balagué et al. 2012). Unfortunately, individuals with MSDs are too often ignored, and their complaints often misunderstood by healthcare providers. Large population studies have shown that successful management of musculoskeletal pain must occur during the acute phase in order to hinder progression to a more chronic state. Adoption of broader standards of care for these conditions, particularly in low-resources areas, is needed (Walsh et al. 2008). This is especially the case when MSDs are co-morbid with other health conditions. For example, research has shown that MSDs are closely associated with mental health and physical disability. Among older people with MSDs, depression is common, and is associated with functional disability (Punzi et al. 2010). Studies have shown that in older adults, depression and pain are better predictors of disability than findings from radiographic imaging. These findings can inform the development of practice guidelines for screening for other co-morbid conditions that might improve the overall health of the person with MSDs (Punzi et al. 2010).

Regarding the prevention of known modifiable risk factors for MSDs, practice efforts should focus on new ways to prevent and control obesity and exposures to mechanical demands in the workplace. However, little has been done globally, nationally, or regionally to systematically address obesity (Popkin 2006). From the 1980s to 2008, trends in the mean population BMI have varied substantially between nations. Developing interventions and drafting policies that modify this observed increase in BMI by targeting these modifiable risk factors are greatly needed in most countries (Finucane et al. 2011).

Practice efforts to address MSDs should include education on diet. Two noteworthy country efforts can be seen in Finland and South Korea (Holveck et al. 2007). Finland has been reported as one of the countries that have made efforts in the direction of using intersectoral collaboration (Pietinen et al. 2010). They have developed an integrated national price and food-labelling policy coupled with educational programmes on diet and nutrition as well as advocacy efforts from select organizations. A second example is South Korea, which has long promoted the use of a traditional diet rich in vegetables and low in fat—very distinct from observed trends in other middle-income countries that have experienced a Westernized shift in dietary consumption (Lee et al. 2012). Over the years, the South Korean government has provided educational

community workshops to new brides on how to prepare traditional dishes and avoid incorporation of Western-style dishes. These efforts have resulted in lower obesity levels and lower intake of energy-dense foods that would be expected from a high-income level country.

Regarding treatment options and practice, there is a need to translate what is already known scientifically to guidelines for clinicians. In the advent of the information age, healthcare professionals can easily become bogged down with multiple sources of information from professional organizations, drug developers, and scientific journals. Data from all these sources could be combined, digested, and presented in a more systematic fashion so that the end user (i.e. healthcare professionals) can benefit from a uniform and up-to-date source of information on best practices to treat MSDs. For example, significant advances in our understanding of the evaluation of quality of life among patients with arthritis and its effect on disease progression have been studied. Translating our basic and clinical science knowledge base into real-world bedside practices should be warranted (Punzi et al. 2010). Therapeutic modalities that are currently available have been largely ineffective due to deficiencies in global MSD management.

Consider access to healthcare, where efforts need to be made so that available treatments permeate all regions. This is, of course, related to the financing aspect mentioned earlier. For example, among rural regions of the developing world, access to joint replacement surgery is scarce and likely leads to a large number of older adults living with high-grade degenerative joint disease and poor quality of life.

Despite access to new information that is made readily available to healthcare providers in developing countries, other barriers may be present (Turner 2009; Doughty et al. 2010; Vargas et al. 2010; El-Jardali et al. 2012). For example, in order to minimize the sequelae from a bout of LBP, healthcare providers in developing countries could incorporate the use of evidence-based guidelines to standardize their management approach and improve MSD treatment outcomes in their community setting. However, despite the progress made in the past two decades in developing and updating guidelines, and adapting them on a national basis, uptake by healthcare providers is not optimum (Global Alliance for Musculoskeletal Health 2014). There are challenges with implementing guidelines in low-resource setting, including the use of specific drugs or technologies that might not be readily available in those areas, as well as pressure from industry or healthcare providers who challenge changes in medical and public health practice (Balagué et al. 2012).

Note

1. From the Operations Manual of the GBD 2010 estimates: musculoskeletal diseases include M00–M85 (arthropathies, systemic connective tissue disorders, dorsopathies, soft tissue disorders, disorders of bone density and structure), M87–M99 (other osteopathies except osteomyelitis, chondropathies, and other disorders of the musculoskeletal system and connective tissue). Rheumatoid arthritis includes M05–M06 (seropositive rheumatoid arthritis and other rheumatoid arthritis). Osteoarthritis include M15–M19 (polyarthrosis, coxarthrosis (arthrosis of hip), gonarthrosis (arthrosis of knee), arthrosis of first carpometacarpal joint, other arthrosis. Back pain includes M46.9 (inflammatory spondylopathy, unspecified), M47 (spondylosis), M48 (other spondylopathies), M48.1 (ankylosing hyperostosis (Forestier)), M48.2 (kissing spine), M48.8 (other specified spondylopathies), M48.9 (spondylopathy, unspecified), M50–M54 (other dorsopathies—including cervical disc disorders, including LBP). Gout includes M10 (idiopathic gout). Other musculoskeletal disorders include M00–M02, M08, M11–M13, M20–M46 (except M46.9), M48 (except M48.0, M48.1, M48.2, M48.8, and M48.9), M60–M85, and M87–M99.

Neurological diseases, epidemiology, and public health

Walter A. Kukull and James Bowen

Introduction to neurological diseases, epidemiology, and public health

Included in this chapter are brief descriptions of headache, traumatic brain injury (TBI), epilepsy, dementia, peripheral neuropathy, parkinsonism, and multiple sclerosis (MS). Diagnosis is critical to epidemiological study but is often difficult because of long, preclinical undetectable periods. Clinical criteria rather than pathological evidence can lead to misclassification of disease and spurious inferences. To some extent biomarkers are becoming accepted as a preclinical indicator of disease or a means to add diagnostic certainty among the symptomatic.

Population-based studies are the best method to avoid spurious, biased, or non-generalizable results, but for most neurological diseases these are seldom performed. Selecting 'control' subjects from the same base that gave rise to the cases is methodologically essential but often a luxury ignored by investigators. Cohort studies must start with people free of disease but if preclinical detection of disease process is not possible, risk factor associations may be severely biased.

Determination of risk factor exposure, and estimating whether it may have occurred during a time window which had potential to result in the disease in question (and not to have resulted from the disease) is critical. In acute TBI this becomes obvious, while for Parkinson's disease (PD), which may have a 20-year preclinical period, it is cryptic. Researchers seldom have records, biological specimens, or even accurate self-report sufficient to establish historical exposure patterns. Biological markers of exposure (except for genotype) are occasionally employed in cancer studies (e.g. DNA adducts), are seldom available for neurological diseases, but may provide some hope for the future. Biopsy is seldom feasible and autopsy results reflect cross-sectional cumulative effects of disease, leaving the picture additionally confusing.

In less developed countries, the problems of diagnosis and exposure measurement grow in magnitude. Differences in available facilities and local practices are likely the easiest to overcome. Addressing political concerns and suspicions to gain cooperation necessary to begin a study may take additional time and preparation.

Headache

Clinical overview of headaches

The pathogenesis of most headaches is poorly understood. The nosology of headaches is based on the cause when known and the clinical picture when the cause is unknown. The International Classification of Headache Disorders (ICHD), second edition, is the most commonly used system of classifying headaches (Headache Classification Subcommittee of the International Headache Society 2004) (Box 8.10.1). It will soon be updated to ICHD-III. This system classifies individual headaches, so patients may have more than one type of headache. In fact, most headache patients have more than one type of headache. Headaches associated with neurological or systemic diseases are comparatively rare. Idiopathic conditions are far more common and include migraine (with or without aura), tension-type headaches, and cluster headaches. Because these idiopathic headaches are the overwhelming majority, they have the greatest impact on epidemiological studies.

Migraine without aura, previously named common migraine, is an episodic headache that may be unilateral or bilateral. Some people have throbbing pain while others have constant non-throbbing pain. Nausea, vomiting, or diarrhoea may occur. The pain often builds over a few hours. The typical length of the headache is 4–72 hours.

Migraine with aura, previously named classic migraine, has an aura consisting of an alteration of neurological function that usually precedes the headache. This commonly consists of a central area of visual loss surrounded by a rim of shimmering light (scintillating scotoma). Non-visual auras may include paraesthesias, numbness, weakness, aphasia, or vertigo. Auras usually precede the headache by about 20 minutes, though timing may vary. The headache is most commonly, though not always, unilateral, throbbing, and often associated with nausea and vomiting. It typically lasts a few hours. It may have premonitory symptoms preceding the headache and aura.

Tension-type headaches, the most common type of headache, are usually bilateral with a sensation of pressure or a tight band around the head. They are less likely to have premonitory symptoms or nausea or vomiting. They do not have auras.

Box 8.10.1 International Headache Society, abbreviated classification of headache

1. Migraine
 - 1.1 Migraine without aura
 - 1.2 Migraine with aura
2. Tension-type headache
3. Cluster headache and chronic paroxysmal hemicrania
4. Miscellaneous headaches unassociated with structural lesion
5. Headache associated with head trauma
6. Headache associated with vascular disorders
7. Headache associated with nonvascular intracranial disorder
8. Headache associated with substances or their withdrawal
9. Headache associated with noncephalic infection
10. Headache associated with metabolic disorder
11. Headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Cranial neuralgias, nerve trunk pain, and deafferentation pain
13. Headache not classifiable

They usually last longer than migraine headaches, typically an entire or several days. They build up more slowly than migraine headaches.

Cluster headaches are named after the tendency to occur in clusters lasting weeks to months. However, other types of headaches may also occur in clusters and the diagnosis is based on the characteristics of the headache rather than the clustering. The headache develops abruptly. During a cluster, it usually occurs between one and eight times a day, often at the same time of day. The pain is more short-lived than that of other idiopathic headaches and generally subsides within 3 hours. The pain is often more severe than that seen with migraine and patients are often agitated during the attack.

In a single patient, less severe headaches tend to be tension-type while more severe headaches are migraine. Over time a patient's headaches often change from classic migraine in youth to tension-type headaches in middle age. Headache frequency may increase with age, becoming chronic daily headaches. Some term these headaches as 'transitioned migraines'. This term is not included in the ICHD and many of these cases are actually due to medication overuse.

Prevalence of headaches

Case definition, sample characteristics, methodology, and analytic designs have differed, sometimes substantially, raising questions

of comparability. One-year prevalences vary from 20–90 per cent (all headaches), 3–24.6 per cent (migraine), 9.8–72.3 per cent (tension-type), and 0.5–7.3 per cent (chronic headache) (Stovner et al. 2007).

Several studies have evaluated the prevalence of migraine, reflecting the availability of validated survey instruments for this disease (Natoli et al. 2010). The 1-year prevalence of migraine is approximately 12 per cent and appears to be stable over time (Linde et al. 2011). Prevalence peaks at 30–39 years of age, and is higher in white people and those with lower incomes (Lipton et al. 2007). Less than half report their migraines to a physician and approximately 40 per cent of these did not receive a correct diagnosis (Lipton et al. 1998). Susceptibility to migraine may be affected by ethnicity since migraine appears to be more common in Caucasians compared to Africans, African Americans, or Asian Americans (Osuntokun et al. 1992; Stewart et al. 1996).

There are far fewer studies on tension-type headaches, though it is the most common type of headache. Up to 89 per cent of people suffer tension-type headaches at some time, but for most this is infrequent (Kaniecki 2012). About 25 per cent have weekly tension-type headaches and 2–3 per cent chronic tension-type headaches (Lyngberg et al. 2005a). The prevalence appears to be increasing, though the factors leading to this are not entirely clear. About half of people with tension-type headaches improve within a decade (Lyngberg et al. 2005b). Chronic daily headache from medication overuse is increasingly recognized (Tepper 2012).

Cluster headaches are the least common of the idiopathic headache disorders. Prevalence ranges from 0.056 to 0.338 per cent (Tonon et al. 2002; Katsarava et al. 2007).

Familial and genetic risks of headaches

Genetic influences on migraine have investigated principally familial aggregation and twins. Studies of single genes responsible for familial hemiplegic migraine provide insight into migraine pathophysiology (Ward 2012). The overall lifetime prevalence of migraine with aura for monozygotic (MZ) and dizygotic (DZ) twins is 7 per cent, similar to population surveys (Gervil et al. 1999; Ulrich et al. 1999). Concordance in MZ twins is 34 per cent compared to 12 per cent for DZ twins. For migraine without aura the concordance for MZ twins is 28 per cent and 18 per cent for DZ. This indicates a potential genetic contribution but modifying environmental influences must also be important. Concordance is higher for MZ than DZ twins whether raised together or apart, and about 50 per cent of the variance is explained by genetic factors with the remaining half 'non-shared environmental factors', and measurement error (Ziegler et al. 1998; Russell et al. 2007).

The relative risk (RR) of migraine in first-degree relatives of migraineurs is 1.88 compared to a control group (Stewart et al. 2006). The RR was higher in relatives of those whose headaches began before 16 years of age (RR = 2.50) than those whose headaches began later (RR = 1.44). The risk in relatives of those with severe headaches had a relative risk of 2.38 (95 per cent confidence interval (CI) 1.56–3.62) while relatives of those with less severe pain had a relative risk of 1.52 (0.99–2.34). Individual genes responsible for migraine have not been identified, though some linkages have been found in genome-wide association studies (GWAS) (Chasman et al. 2011).

Risk factors for headaches

Stress or psychological factors are often cited as contributing to tension-type headaches. However, the frequency of these factors is similar in patients with migraine and tension-type headaches. With chronicity, psychological changes increase in frequency, suggesting that psychological issues are secondary to chronic headaches rather than causative. There is an increased risk of depression in migraineurs and also an increased risk for migraine among those with prior depression, suggesting the two disorders may have mechanisms in common. The issues of migraine and depression have been reviewed (Frediani and Villani 2007).

Chronic daily headaches are more common in women, white people, and those with less education. An improvement in headache frequency after 1 year was more common in those with higher education, non-white people, and those who were married (Scher et al. 2003). However, in adolescents with a family history of migraine, migraine prevalence is the same in low- versus high-income groups suggesting that genetic factors overwhelm environmental risk factors in those genetically susceptible (Hagen et al. 2002). One of the strongest risk factors for headaches is prior headaches (RR = 4.15) (Boardman et al. 2006). Pain in other areas of the body is associated with headache (RR = 1.43).

Stroke and migraine

Migraine has been associated with stroke in a number of studies (Alhazzani and Goddeau 2013). Additional study will be needed to adequately describe the true relationship between migraine and stroke.

Costs and public health impact of headaches

The estimated 23 million people with migraines in the United States may miss 150 million workdays each year with an associated cost of up to US\$17 billion (Cady 1999; Hu et al. 1999). Many more people suffer with decreased effectiveness at work than actually miss work days (Schwartz et al. 1997). In Europe, costs of headaches are substantial with mean per-person annual costs of €3561 for medication overuse, €1222 for migraine, and €303 for tension-type headaches (Linde et al. 2012). Health-related quality of life is lower in those with migraine, and this is related to the frequency of attacks (Wang et al. 2001). There are many challenges in making cost determinations due to limits on available epidemiological data (Leonardi et al. 2005). However, the best estimate suggests that migraine accounts for 1.4 per cent of all years of healthy life lost worldwide. It is the 19th leading cause of years of healthy life lost in men and 12th in women. This major public health issue deserves continued attention.

Traumatic brain injury

Clinical overview of traumatic brain injuries

TBI is commonly divided into two categories by mechanism of action: (1) penetrating or (2) closed head injuries. These also may be characterized as resulting from direct contact injuries or from concussive 'acceleration deceleration' types of injuries (Werner and Engelhard 2007). Among penetrating injuries, greater tissue damage is caused by high-velocity penetrating objects than by lower-velocity ones. Both penetrating and closed injuries may perturb or impair cerebral blood flow (CBF) leading to ischaemia

and altered cerebral metabolism. Impaired CBF resulting from cerebral vasospasm predicts poorer outcome and may occur in approximately 30 per cent of TBI cases (Werner and Engelhard 2007). Brain contusions may lead to both blood vessel and cell membrane injury resulting in vasogenic or cytotoxic oedema. Hydrocephalus may develop due to blockage of the routes of normal cerebrospinal fluid (CSF) flow. Finally, closed head injuries may lead to diffuse axonal injury. Diffuse axonal injury results in balls of axonal material occurring at axon transection sites or sites of altered axonal flow. Intracranial pressure monitoring is a concern; however, a recent trial does not support it as superior to other forms of neurological monitoring (Chesnut et al. 2012). Neurological damage due to TBI may grow after the injury because of impaired cerebral perfusion and other factors.

For mild head injuries, including skull fracture, concussion, and unspecified intracranial or head injury (Bazarian et al. 2005), the severity of the injury is usually measured by the degree of post-traumatic amnesia. More recently, concerns for chronic traumatic encephalopathy (CTE) due to repetitive mild head injuries have become a substantial concern as a cause of dementia and dysfunction years later, especially for those engaged in contact sports (Baugh et al. 2012; McKee et al. 2013). Head injury severity is usually classified by the Glasgow Coma Scale: scores of 13–15 are minor, 9–12 are moderate, 5–8 are severe, and 4 or less are very severe; and by length of coma (Jennett et al. 1976; Sherer et al. 2007).

Incidence and prevalence of traumatic brain injuries

The US Centers for Disease Control and Prevention (CDC) estimates that 1.57 million people (95 per cent CI 1.37–1.77 million) suffered a TBI in 2003 in the United States (538.2 per 100,000 population), approximately 51,000 of those resulted in death (TBI mortality 17.5 per 100,000 population) based on all reported emergency department visits, hospitalizations, and deaths. Cassidy et al. (2004) compiled a review of more than 160 published studies and found that approximately 70–90 per cent of all treated TBIs are likely to be mild which results in an expected rate for *treated* mild TBI of 100–300 per 100,000 population. Almost paradoxically, Rivara et al. found that among children with TBI the burden of disability caused by TBI was primarily due to mild TBI (Rivara et al. 2012). TBI incidence among children aged 0–4 was the highest of all age groups at 1188.5 per 100,000, while hospitalization and death rates were highest among those aged 65 and older. Falls accounted for 32 per cent of TBIs, motor vehicle traffic for 19 per cent, struck by/against events 18 per cent, and assaults 10 per cent. Men experienced about a 1.5 times greater rate of TBI than women. TBI hospitalization associated with assault was nearly six times higher for males than females across all age groups from 15 to 64. Sadly, females aged 0–4 years showed approximately twice the TBI hospitalization rate due to assault as any other female age group (Rutland-Brown et al. 2006).

Risk factors of traumatic brain injuries

Falls

Falls are perhaps the most common cause of TBI and incidence increases dramatically with advanced age. Californian 1996–1999 age-specific rates ranged from 13.6 per 100,000 in people aged less

than 65 years, to 41.8 in those aged 65–74, to 104.0 in those aged 75–84, and then more than doubled to 223 per 100,000 among those aged 85 years or older (CDC 2003). Use of four or more medications may significantly increase risk of TBI from falling.

Falls are also an important cause of TBI among the very young. The 15-State CDC surveillance system allowed calculation of TBI hospitalization rates due to unintentional falls for children aged 0–11 months compared to those aged 12–23 months. Fall-related TBI hospitalizations were 71.5 per 100,000 person-years in the younger group as compared to 36.5 per 100,000 person-years in the older group. Although TBI in toddlers and young children is due primarily to household or playground falls, motor vehicle accidents are the predominant cause in older children (Keenan and Bratton 2006).

Vehicle accidents

A report constructed by the US CDC based on TBIs which led to emergency department visit, hospitalization, or death in 2003, showed that overall, motor vehicle accidents (19 per cent) were second only to falls (32 per cent) as a cause of TBI based on a total overall estimate of TBI of between 1.37 million and 1.77 million events (Rutland-Brown et al. 2006). Injuries resulting from motor vehicle accidents, whether occurring to occupants or as pedestrian or cyclist versus motor vehicle, result in many of the more severe TBIs. Mandatory seat belt and child seat laws could have an effect on reducing occupant injuries, while bicycle and motorcycle helmet use may reduce the occurrence of TBI in those constituent categories.

Violence

Assaults are estimated to have accounted for approximately 10 per cent of the TBIs occurring in the United States in 2003 or roughly 160,000 TBIs (Rutland-Brown et al. 2006).

As much as 20 per cent of TBI may be the result of violence, roughly half of these are due to firearms. The age group at highest risk is 15–24 years. While males appear to be more likely to sustain an injury due to violence, women may be more likely to die as a result. The incidence of firearm-related injury or death was 42 per 100,000. The homicide rate varies dramatically by age and ethnic group. Overall it was about 14 per 100,000, but rose to 73 per 100,000 in African American males and further to 164.2 per 100,000 among 15–34-year-old African American males.

Abuse and domestic violence are important causes of TBI among women and among children (Monahan and O'Leary 1999; Valera and Berenbaum 2003; Banks 2007). Monahan estimates that about 35 per cent of the 2–3 million women battered each year by their domestic partner sustain TBI as a result. Keenan et al. (2003) found that physical abuse may be the most frequent cause of TBI in children aged less than 2 years with an estimated incidence rate of approximately 17 per 100,000 person years; infants had a higher incidence than older children and boys were at somewhat greater risk than girls.

Sports

Sports injuries account for a relatively small proportion of serious TBI. Between 2001 and 2005 approximately 208,000 emergency department visits each year in the United States were the result of sports and recreational activities (2007). The majority of these injuries occurred among children aged 10–14 years, closely followed by those aged 15–19 years. Hospital admission resulted in approximately 10 per cent of these incidents, but most such TBIs resolve spontaneously.

However chronic repetitive TBI can lead to CTE (McKee et al. 2013) resulting in long-term disability (Rivara et al. 2012).

War and sociopolitically directed violence

By the end of 2012 approximately two million US and UK men and women will have served in the wars in Iraq and Afghanistan resulting in thousands of deaths and tens of thousands of severe injuries. Injuries related to explosive blasts may account for many or most of these (Warden 2006) and effects of these types of injuries years later could have important individual and public health consequences for many years to come. Not only do blasts account for much of the observable and immediate injuries, but they may also lead to more mild or unreported TBI that can be coupled with post-traumatic stress disorder (PTSD) (Hoge et al. 2004; Holbrook et al. 2005; Okie, 2005). People who may have experienced TBI or blast-related TBI could ultimately be at higher risk for dementia as they enter ages 60–80.

Implications for public health

The potential years of productive life lost due to TBI varies with its cause, and causes are differentially age-related. The risk of seizures following TBI is increased up to 17-fold in patients with severe injuries (Annegers et al. 1998). While injuries related to motor vehicles and falls are the most common, those who are most severely affected, have the poorest outcomes, and require the most continuing care, tend to be the very young and the elderly. Sports injuries tend to be mild and resolving, but in the case of repetitive injury may result in serious sequelae years later. War-related TBIs could be the source of an unexpected public health burden because of the large numbers of soldiers serving and the high incidence of blast and other injuries coupled with the development of PTSD, psychiatric symptoms, cognitive deficits, and degenerative dementias or other neurological disorders.

Epilepsy

Clinical overview of epilepsy

The International League Against Epilepsy (ILAE) classification system is currently the most commonly used means of organizing epileptic syndromes (Box 8.10.2) (Engel 2006). Characteristics of individual seizures are divided into location-related seizures (formerly named partial or local seizures) that begin in a localized part of the brain, and generalized epilepsies that begin diffusely in the brain. The areas of brain initially involved determine the symptoms of location-related seizures. Location-related seizures may (simple partial) or may not (complex partial seizures) be associated with altered consciousness. They may secondarily generalize after a focal onset.

Generalized seizures (formerly *grand mal*) begin in widespread areas of the brain. The most common type of generalized seizure is noted for muscle stiffening followed by jerking (tonic-clonic). Absence seizures (formerly *petit mal*) consist of brief episodes of staring and lack of responsiveness. Myoclonic seizures involve brief jerks of muscles rather than repetitive clonic movements. Tonic seizures have generalized muscle stiffening. Atonic seizures involve sudden loss of muscle tone. The ILAE classification has limitations for epidemiology use because of its emphasis on syndromes and absence of aetiological factors including genetics (Camfield 2012).

Box 8.10.2 The International League Against Epilepsy classification of epileptic seizures**I. Partial (focal, local) seizures**

- A. Simple partial seizures
- B. Complex partial seizure (with impairment of consciousness)
- C. With impairment of consciousness at onset
- D. Partial seizures evolving to secondarily generalized seizures

II. Generalized seizures

- A. Absence seizures
- B. Myoclonic seizures
- C. Clonic seizures
- D. Tonic seizures
- E. Tonic-clonic seizures
- F. Atonic seizures

III. Unclassified epileptic seizures

Incidence and prevalence of epilepsy

Aspects of epilepsy epidemiology have been reviewed (Thurman et al. 2011). Epidemiological studies of epilepsy are challenged by the difficulty in making a correct diagnosis and the sophisticated technology required for proper diagnosis and classification. A substantial number of patients diagnosed with epilepsy do not have seizures on careful testing (Uldall et al. 2006). There is also difficulty with standardizing case ascertainment with markedly different prevalence rates using different definitions of epilepsy (Svendsen et al. 2007).

In a meta-analysis the overall incidence of epilepsy was 50.4/100,000, with 81.7 in low/median-income populations and 45.0 in high-income populations (Ngugi et al. 2011). Population-based and prospective studies had higher incidence rates than clinic-based and retrospective studies. Incidence is higher in children but both incidence and prevalence decrease with calendar time among children and increase among the elderly (Hauser et al. 1996; Hirtz et al. 2007). Others found an increased incidence in men, older people, black people, and those with pre-existing disability or co-morbid conditions (Kaiboriboon et al. 2013). A study of children in the United Kingdom found a cumulative incidence of epilepsy by age 5 to be 1 per cent in those born between 1994 and 1996 and 0.53 per cent in those born between 2003 and 2005 (Meeraus et al. 2013). The annual incidence declined by 4 per cent/year from 2001 to 2008. However, a longitudinal study from Rochester, Minnesota, United States, found a slightly higher estimate of epilepsy incidence over time (Zarrelli et al. 1999).

The prevalence of epilepsy is estimated to be 7.1/1000 (Hirtz et al. 2007). However, prevalence varies in different regions. In an African population, a greater than twofold variability was found in prevalence across regions (Ngugi et al. 2013). Younger patients more commonly had seizures attributable to trauma and older patients to infectious causes. There were similar findings between

regions of Taiwan (Chen et al. 2012). In general, poor countries have more than twice the burden of epilepsy compared to higher-income regions with much of the difference explained by preventable infections, perinatal care, and trauma (Newton and Garcia 2012). Differences in study methodology, survey methods, case definition, the availability of sophisticated medical technology in a community, and cultural differences make epilepsy prevalence studies particularly challenging.

Mortality of epilepsy

People with epilepsy may experience two to three times the risk of death as their unaffected counterparts (Sperling et al. 1999). The standardized mortality ratio for people with recurrent seizures was approximately fourfold higher than expected. A longitudinal study found a threefold excess in all-cause mortality, and a sevenfold increase among those under age 20 (Shackleton et al. 1999). Some of the risk of death in epilepsy reflects underlying diseases like brain neoplasms and cerebrovascular disease. However, there is also an increased mortality compared to the non-epileptic population due to accidents (often drowning and burns) and suicide (Lhatoo and Sander 2005). Sudden unexplained death in people with epilepsy (SUDEP) is increasingly recognized as an important cause of death in epilepsy. This increases with the duration and severity of epilepsy (Devinsky 2011). It is more common in adults. The incidence of SUDEP varies from 0.09–2.65 in community samples, 1.2–5.9 in epilepsy centres, and 6.0–9.3 among patients referred for surgery for epilepsy. In a population-based cohort of children with epilepsy who were followed for 40 years, SUDEP occurred in 9 per cent, accounting for 38 per cent of all deaths.

Infectious causes of epilepsy

In developing countries, infections are a much more important cause of epilepsy than in the United States and Europe. Parasitic, bacterial, and viral infections combine with hereditary factors, perinatal damage, head trauma, and toxic exposures to contribute to high rates of epilepsy in these countries (Newton and Garcia 2012). An example of an important infectious risk factor is *Taenia solium* cysticercosis (pork tapeworm) which causes neurocysticercosis. This is a major cause of epilepsy worldwide (Del Brutto 2012). Other infectious causes of epilepsy are various febrile illnesses, particularly encephalitis, and malaria.

Genetics of epilepsy

Genetics are increasingly recognized as a contributor to epilepsy risk. Over 200 genes are now associated with epilepsy and include monogenic, complex, mitochondrial, chromosomal, and imprinting. Screening methods have been proposed for evaluating patients with epilepsy (Lemke et al. 2012). Epigenetic factors may also influence circuit excitability and neurogenesis in epilepsy (Roopra et al. 2012). Many types of epilepsy are now recognized as genetic disorders. However, these are rare forms of epilepsy and the genetic contribution to the majority of cases remains unexplained. First-degree relatives of people with epilepsy have a two- to fourfold increase in epilepsy risk (Annegers et al. 1982). A number of epilepsies have now been shown to be due to channelopathies, mutations in ion channels (Avanzini et al. 2007). It is expected that many more genes associated with epilepsy will be identified.

Costs and public health burden of epilepsy

Only 42 per cent of those over age 18 with epilepsy are employed compared to 70 per cent of those without epilepsy (Libby et al. 2012). People with epilepsy have higher work absences. Holding other variables constant, people with epilepsy had a loss of productivity of \$9504 compared to people without epilepsy. Indirect costs may account for 85 per cent of the total, and the largest share of direct costs is attributable to patients with intractable epilepsy (Begley et al. 2000). Seizure frequency is inversely associated with health-related quality of life (Leidy et al. 1999). Seizure-free individuals report a quality of life similar to the general population; however, more seizures lead to a poorer quality of life, regardless of additional co-morbidity, and irrespective of gender. Effective seizure control appears to be important in reducing costs as well as increasing patient quality of life.

Dementia

Clinical overview of dementia

Dementia presents with a progressive loss of a person's usual and customary cognitive function from any of several domains. This often begins with memory problems in Alzheimer's disease (AD) but could also begin with language deficits or disinhibition in frontotemporal lobar degeneration (FTLD), or with deficits in executive function in vascular cognitive impairment, or with sleep disorders or hallucinations in Lewy body disease. Regardless of the beginning domain, cognitive impairment associated with most dementia tends to progress and affect other cognitive domains with time. Dementia often includes behavioural changes, such as agitation, wandering, personality change, or depression, as well as sleep disturbances and psychiatric symptoms. As knowledge of specific subtypes of dementia has grown, the research community has come to rely more on specific clinical criteria for those subtypes. While the DSM (American Psychiatric Association 1994) criteria were originally constructed to provide for mutually exclusive diagnostic subgroups, it is now widely acknowledged that more than one underlying 'brain disease' may coexist and lead to the expression of dementia.

Dementia has many causes including neurodegenerative, vascular, infectious and traumatic. Among the neurodegenerative dementias that predominate with ageing are AD, Lewy body disease (aka dementia with Lewy bodies (DLB) or PD dementia) and FTLD dementias. Cerebrovascular disease may coexist with and contribute to any of these or may be a primary cause on its own as vascular dementia (VaD). Prion disease, and associated spongiform encephalopathies (e.g. Creutzfeldt–Jakob disease (CJD) and variant CJD) are rare, but potentially transmissible from ingestion of animal tissue or from contact or transplantation of human tissue. Other disorders and insults which can result in dementia include drug-induced conditions, alcoholism, Huntington's disease, subdural hematoma, brain tumours, hydrocephalus, vitamin B₁₂ deficiency, multiple medical conditions, hypothyroidism, and neurosyphilis.

Criteria for the clinical diagnosis of AD dementia (McKhann et al. 2011), mild cognitive impairment due to AD (Albert et al. 2011), and preclinical AD (Sperling et al. 2011) emphasize the addition of biomarkers to characterize the underlying disease pathology. Amyloid imaging and CSF assays for amyloid-beta

protein, tau, and phospho-tau proteins are of greatest importance in preclinical AD because no cognitive symptoms are present. Neuropathological criteria formerly were the clinical-pathological NIA-Reagan consensus criteria (1997) ranking the likelihood that pathological features (amyloid plaques and neurofibrillary tangles) existed in sufficient frequency to have caused the clinically observable dementia. New neuropathological criteria (Hyman et al. 2012) form a diagnosis based only on pathological features present, regardless of clinical dementia. The research community thus has taken a major step to define AD by pathology that is present (in both clinical and neuropathological criteria) and has recognized formally that asymptomatic AD occurs. This opens the door to conceptualization of secondary prevention.

Mild cognitive impairment

Clinically observable cognitive decline, not yet at the level meeting criteria for dementia, has been called mild cognitive impairment (MCI) (Petersen 2004). As a prodrome to dementia or simply an impaired state, it may have many underlying causes; MCI itself is not an aetiological diagnosis, but a characterization of affected cognition. The portion of MCI which is due to AD has now been provided with formal clinical criteria and biomarker indications (Albert et al. 2011). Recognition that the disease process in AD may have been underway for as many as 10–25 years and is potentially detectable by CSF biomarkers and/or amyloid imaging (Sperling et al. 2011; Bateman et al. 2012) changes the way epidemiologists should look at risk factor studies and the timing of exposures sufficient to cause disease onset. Pathological onset also explains in part why potential treatments given to mild or moderately impaired subjects would have little chance of success. What would a rehabilitative treatment for dementia due to AD potentially look like? Possibly in addition to slowing or stopping the formation of pathology, it would need to facilitate neuronal regeneration, branching, and connections, if recovery might happen.

Tracking and describing prognostic factors associated with cognitive decline has been the subject of many investigations. However, in the case of AD and probably other underlying causes, the timing and course of decline may be more likely to be tied to the frequency and location of damage due to pathology than it might be to education, for example. Determining and describing potentially modifiable factors which might change the course of decline in those with symptomatic disease, is one of the major challenges of AD and other dementias. The original criteria for MCI (Petersen 2007) allowed MCI to represent a variety of aetiologies in addition to AD. On the non-amnestic side, it could easily include vascular cognitive impairment as well as cognitive impairment due to FTLD or Lewy body disease. However, the amnestic side of MCI is regarded by many to represent primarily early AD (Morris et al. 2001; Morris and Cummings 2005; Morris 2006). People diagnosed with MCI also are known to recover and not go on to develop dementia. The potential progression of cognitive decline is described well by Sperling et al. (2011) as a continuum, rather than reclassification into separate categories of dementia or MCI.

Dementia and Alzheimer's disease

Prevalence and incidence of dementia and AD

Almost two decades ago, Evans and colleagues reported prevalence estimates for dementia and AD based on a community

study in East Boston, Massachusetts, United States (Evans et al. 1989), placing an heuristic upper bound on estimated prevalence of dementia in United States' communities: rising from 3 per cent among those 65–74 years of age to 47 per cent in those over age 85, with over 80 per cent of the observed dementia classified as AD. Evans later projected that 10.3 million people would have AD in the year 2050. A recent meta-analysis of prevalence studies worldwide (Prince et al. 2013) shows remarkably similar age-specific prevalence and age-adjusted summary prevalence across all regions of the world, with the lowest prevalence being in sub-Saharan Africa and possibly the highest in Latin America and the Caribbean. A total of 35.6 million people worldwide were estimated to be demented in 2010; 15.94 million of those in Asia. By 2050, it is estimated that 115.38 million people will be living with dementia. An estimated \$420 billion was spent on dementia care in the United States and Western Europe in 2010; worldwide \$604 billion were spent (Wimo et al. 2013). An incidence rate meta-analysis (Jorm and Jolley 1998) gathered data from 23 studies. Incidence was estimated for Europe, the United States, and East Asia; dementia, AD, and VaD rates were computed. Incidence rates for clinically diagnosed dementia rose from 3.6 per 1000 person-years (aged 65–69) to 37.7 per 1000 person-years (aged 85–89) in Europe and from 2.4 to 27.5 per 1000 person-years for the same age groups in the United States.

Similarly Rocca et al. (1998) re-analysed dementia and AD incidence data for 1975 through 1984 and observed that annual age-specific incidence rates have appeared to stay quite stable with time during that interval. Launer et al. (1999), combining cohorts enrolled in Denmark, France, the Netherlands, and the United Kingdom, determined that the incidence of dementia rose from 2.5 per 1000 person-years at age 65–69 to 85.6 per 1000 person-years in those aged 90 and older; while AD rose from 1.2 per 1000 person-years to 63.5 per 1000 person-years across the same age groups.

Suppose that the incidence of AD were estimated by the development of positive biomarkers including asymptomatic people. How would such a change shift the age distribution and the incidence rates?

While the tendency has been to attempt to count primary cause or pathologically 'pure' cases, dementia causing aetiologies (e.g. Alzheimer, vascular, Lewy body, FTLT) appear to commingle frequently in community dwelling cases. This commingling is consistent with the view that these diseases may exist as multiple amyloidoses resulting from aggregation of misfolded proteins (Morimoto, 2006).

Distinguishing between normal people, those with MCI and those asymptomatic people with occult dementia-related pathology, is now possible to some degree as noted in Sperling et al. (2011) based on newly developed neuroimaging techniques (Klunk et al. 2003; Mathis et al. 2003; Small 2004) and CSF biomarkers. These 'biomarkers' may provide important clues about pathological onset of disease as well as inform the study of risk factors and critical periods of exposure prior to disease onset (Mintun et al. 2006; Bacskai et al. 2007; Fagan et al. 2007; Rowe et al. 2007).

Risk (and protective) factors for AD

The attempt to identify environmental risk factors for AD has been disappointing and conflicting, for methodological as well as biological reasons. Because the pathological disease may begin

from 10–25 years prior to any symptoms, the time window for exposures which could be relevant for onset is shifted even further back in time. Few observational studies were able to place any exposures except for genetic factors in this time range. Thus case-control studies were likely to be methodologically compromised by diagnostic misclassification, as well as ill-timed or missing exposure data. Cohort study designs fare only slightly better because the initial cohort would include asymptomatic people; for example, the base cohort would not effectively exclude prevalent disease, causing diagnostic misclassification. Thus, the risk or protective factors reported by epidemiological case-control or cohort studies to date must be viewed with considerable caution; the notable exception is the genetic risk factor, apolipoprotein E (APOE) $\epsilon 4$ allele. APOE may exert independent effects or it may modify or confound the effect of environmental risk factors (Anonymous 1998; Launer et al. 1999; Mehta et al. 1999).

Higher educational level has been proposed as decreasing risk of AD, but the relationship is complex (e.g. Hendrie 1998; Geerlings et al. 1999; Koepsell et al. 2007). The idea that higher education confers greater 'cognitive reserve' to be accessed when disease strikes is tantalizing, though biologically unsubstantiated. Koepsell et al. in a clinico-pathological study found that there was 'no evidence of larger education-related differences in cognitive function when Alzheimer disease (AD) neuropathology was more advanced', concluding further that 'Higher Mini-Mental State Examination scores among more educated people with mild or no AD may reflect better test-taking skills or cognitive reserve, but these advantages may ultimately be overwhelmed by AD neuropathology' (Koepsell et al. 2007). Quality of early life environment, as measured by number of siblings and area of residence, was associated with developing AD in late life, but educational level was not significantly associated with risk of AD (Moceri et al. 2000).

Anti-inflammatory medications have been studied for their potential protective effect on AD (Breitner 1996; In t'Veld et al. 2001; Szekely et al. 2007). The Alzheimer's disease anti-inflammatory prevention trial (ADAPT) was launched in 2001. The trial enrolled 2625 subjects, aged 70 years or older, and randomized them to placebo, celecoxib, or naproxen sodium treatment arms. The trial itself was stopped early because of an excess of cardiovascular events in the treatment arms. A preliminary analysis based on data available following trial closure showed no significant effect of either celecoxib or naproxen as compared to placebo for the prevention of AD.

Oestrogen replacement therapy as a protective factor has shown a remarkably similar chequered research results history as anti-inflammatory medications, with the bulk of epidemiological evidence favouring protection and a fair amount of biological plausibility also marshalled in its support. Despite this large accumulation of epidemiological and laboratory evidence supporting the potential protective effect of oestrogen against the onset of AD, the Women's Health Initiative Memory Study (a randomized controlled trial of oestrogen and oestrogen plus progestin vs. placebo) showed a statistically significant *increased* risk of dementia among those given the active treatments (Shumaker et al. 2003, 2004). As a potential treatment for AD dementia, results also have shown no effect on AD (Henderson et al. 2000; Mulnard et al. 2000).

Factors related to cardiovascular disease and metabolic syndrome (including diabetes) may have an influence on AD and other dementias even though the exact mechanisms of interaction

may not yet have been elucidated (Launer et al. 2000; Yaffe et al. 2004; Kivipelto and Solomon 2006; Laitinen et al. 2006; Li et al. 2007; Muller et al. 2007). The rationale for this approach appears to be that it is sound medical practice to treat hypertension, high cholesterol, diabetes, and obesity, and if more complete and effective treatment can be accomplished it may also, secondarily, serve to reduce the occurrence of dementia through vascular or other pathways which may or may not directly impact AD pathology.

Genetics and AD

Great progress was made regarding the genetics of AD during the late 1980s and 1990s with the discovery of presenilin-1 and -2 and amyloid precursor protein mutations as familial, autosomal dominant causes and the APOE ϵ 4 allele as a 'risk factor'. Several reviews of AD genetics describing this period of growth in greater detail include: Hardy et al. (1998), Levy-Lahad et al. (1998), St George-Hyslop (2000), and Haass (2004).

The strongest and most consistent genetic risk factor for late onset, non-autosomal dominant AD today is the APOE genotype. The association was first described from Dr Allen Roses' laboratory (Corder et al. 1993; Saunders et al. 1993; Strittmatter et al. 1993). APOE naturally occurs as three different alleles (epsilon 2, epsilon 3, and epsilon 4) which pair to form one of six genotypes for each individual. Genotypes containing the epsilon 4 allele are associated with increased risk of AD; homozygous epsilon 4 greatly increases risk (e.g. greater than eightfold). Since the initial description of increased risk associated with the epsilon 4 allele, many investigators have observed the association. Discussion of APOE genotype is now included in nearly all genetic and risk factor studies of AD, either as a focus or as a potential confounder/effect modifier of an association. Despite the huge volume of studies including the APOE genotype, relatively little is known concerning how the ϵ 2, ϵ 3, and ϵ 4 alleles actually work to influence the risk of AD.

There have been a number of GWAS of AD, using large numbers of subjects (e.g. Hollingworth et al. 2011; Naj et al. 2011), which have identified and replicated a range of new common variants. Recently two important studies have shown an increased AD risk due to TREM2 (Guerreiro et al. 2013) and in African Americans an increased risk associated with ABCA7 (Reitz et al. 2013). Because these and other current GWAS have included strong replication they are regarded as superior to most candidate gene studies that occurred between the mid 1990s and 2010. More such studies have been performed; in addition, data sharing has allowed other investigators to examine associations between these identified loci and clinical characteristics (endophenotypes) such as cognitive decline.

Vascular dementia

VaD is difficult to describe clinically and neuropathologically. The search for 'pure' cases of VaD and AD may have obstructed progress of understanding how these diseases act and interact. Vascular features commonly coexist with AD in the elderly: newer sophisticated imaging and other measures, as well as neuropathology, bear this out (Au et al. 2006). Several different criteria have been developed to diagnose VaD (Chui et al. 1992; Roman et al. 1993; American Psychiatric Association 1994). Much of the pioneering work in the clinical definition and recognition of VaD can be attributed to Hachinski and colleagues. The Hachinski

Ischaemic Score continues to be used to indicate the extent of cerebrovascular involvement in cognitive decline (Hachinski 1994).

Pathologically, VaD is an enigma, because of the lack of clear definitions for white matter damage, infarcts, and lesion location in strategic areas of the brain—VaD, in effect, lacks a pathological gold standard against which to compare the clinical diagnosis or clinical criteria and measure their effectiveness (Murray et al. 2007). Thus, the clinical diagnostic criteria have been shown to be difficult and potentially unreliable in practice, even when applied by well-experienced research investigators (Chui et al. 2000).

Lewy body disease and frontotemporal lobar degeneration

Two additional types of dementia, Lewy body disease (McKeith 2006) and FTLN (Cairns et al. 2007a), have been separated from AD based on their clinical presentations but more specifically on their pathology. Lewy body disease or DLB may be diagnosable in up to 30 per cent of dementia cases. PD is also a 'Lewy body' disease and if Parkinson's cases survive long enough they will become demented as a result (Zaccai et al. 2005; Tsuang et al. 2006). Lewy body disease or DLB often presents with fluctuating cognitive performance, visual hallucinations, REM sleep behaviour disorder, and/or parkinsonism. Memory impairment may not be as prominent in the early stages of the disease as deficits in attention, frontal subcortical skills, and visuospatial ability (Knopman et al. 2001; Korczyn and Reichmann 2006).

FTLD has undergone a revolution in classification since initial work on progranulin (Gass et al. 2006; Rademakers et al. 2007) followed by the careful study of the involvement of TDP-43 (Neumann et al. 2006; Van Deerlin et al. 2010) and the discovery of association with C9ORF72 (DeJesus-Hernandez et al. 2011) includes specific disease subtypes and may be the most frequently occurring dementia in people under the age of 65 (Mackenzie and Rademakers 2007). Behavioural variant frontotemporal dementia (bvFTD) represents a behavioural subtype with changes such as loss of personal awareness, loss of social graces, disinhibition, overactivity, restlessness, impulsivity, distractibility, hyperorality, withdrawal from social contact, apathy or inertia, and stereotyped or perseverative behaviours. The memory loss is variable and often appears to be due to lack of concern or effort. Frontal lobe impairments are notable including abstraction, planning, and self-regulation of behaviour. FTLN may also be associated with parkinsonism or motor neuron disease. Pathologically, approximately 40 per cent of FTLNs are related to mutations in the microtubule-associated protein tau (*MAPT*) gene on chromosome 17 and are therefore 'tauopathies'; these include Pick's disease, corticobasal degeneration, and progressive supranuclear palsy (Rademakers and Hutton 2007; Tolnay and Frank 2007). About 50 per cent of FTLNs are not tauopathies but are reactive to ubiquitin (FTLN-U) rather than mutations in *MAPT* (Mackenzie and Rademakers 2007). Recently, it was discovered that mutations in the progranulin gene, also on chromosome 17, were an important cause of FTLN-U disorders (Baker et al. 2006; Cruts et al. 2006; Gass et al. 2006) including primary progressive aphasia (Mesulam et al. 2007). The pathological protein involved in these disorders as well as in motor neuron disease is TDP-43 (Mackenzie et al. 2006; Neumann et al. 2006; Cairns et al. 2007b; Kwong et al. 2007). These are arguably the most exciting and important findings for dementia and FTLN in recent times. FTLN

is rare compared to AD and even so is thought to be frequently misdiagnosed as a psychiatric disorder because of its early onset and unusual clinical symptoms.

Peripheral neuropathy

Clinical overview of peripheral neuropathy

Though 'peripheral neuropathy' may refer to any disease of peripheral nerves, it usually describes systemic diseases that affect peripheral nerves rather than focal diseases affecting an isolated nerve. Most of these diseases affect longer nerves first with symptoms developing first in the feet and progressing up the legs. Few peripheral neuropathies affect shorter proximal nerves first. By the time symptoms reach the knees, the hands become symptomatic followed by the anterior trunk and crown of the head. Symptoms depend on the type of nerve fibre involved. Involvement of motor fibres leads to weakness, muscle wasting, and hyporeflexia. If longstanding, motor neuropathies may lead to high arches (pes cavus) or hammer toes. Sensory nerve involvement leads to loss of sensation, distorted sensation (dysaesthesias), or spontaneous unpleasant sensations (paraesthesias). Autonomic neuropathies lead to postural hypotension, sexual dysfunction, bowel dysfunction, bladder dysfunction, and gastroparesis. The size of the affected nerve fibre can often be suggested by the history with large fibre disease causing reflex loss, vibration loss, and joint position loss. Small fibre disease often leads to autonomic dysfunction, dysaesthesias, loss of pain sensation, and loss of temperature sensation.

Electrodiagnostic testing is used to diagnose and classify peripheral neuropathies. Nerve conduction velocities can classify peripheral neuropathies into demyelinating and axonal types. Demyelinating neuropathies have disproportionate slowing and increased latencies of nerve conduction speeds. Axonal diseases cause disproportional loss of amplitude with relative preservation of conduction speed. Nerve conduction studies measure only the fast-conducting large diameter fibres. Electromyography (EMG) measures the electrical activity of muscle fibres. A loss of muscle fibre innervation by large myelinated neurons leads to increased insertional activity, positive waves, fibrillation potentials, polyphasic motor unit potentials, and decreased recruitment patterns on EMG. Occasionally, nerve or muscle biopsies are used for diagnosis of polyneuropathies.

Generally, polyneuropathies involve many peripheral nerves and result in autonomic neuropathies, sensory loss, or weakness. Mononeuropathies, as the name implies, involve a single nerve injury or entrapment, for example, carpal tunnel syndrome (CTS) or Bell's palsy. Peripheral nerve disorders are often classified as hereditary or acquired. Charcot-Marie-Tooth syndrome is a well-known hereditary form. Acquired nerve disorders are associated with trauma/compression, diabetes, alcoholism, and other nutritional and metabolic problems. They may also be related to infectious causes such as Guillain-Barré syndrome, leprosy, Lyme disease, or HIV infection; or they may be caused by toxic exposures to metals (e.g. lead, mercury), industrial chemicals, or therapeutic drugs (e.g. antineoplastic agents) (Rowland and Merritt 1995). Little is known about the epidemiology of peripheral neuropathies, though they are common. The few studies that have been conducted find prevalence rates ranging from 2.4 to 8 per cent (Martyn and Hughes 1997). Prevalence increases

considerably with age to 54 per cent of those aged 85 and older (Mold et al. 2004).

Carpal tunnel syndrome

CTS is probably the most common neuropathy. Carpal tunnel release surgery is one of the most common hand surgeries. Occupational CTS from repetitive, higher-impact actions differs from non-occupational CTS by occurring nearly equally among men and women and at a lower mean age (37 vs 51 years) than non-occupational CTS (Franklin et al. 1991). Based on US workmen's compensation records, an incidence of 1.74/1000 full-time equivalent jobs was observed.

In contrast to the occupational incidence, the general population CTS incidence was 3.46/1000 person-years (Nordstrom et al. 1998). The apparent increase in incidence may reflect a true change or may be affected by popular knowledge of the condition and diagnostic suspicion. Prevalence of symptoms in relation to true disease prevalence is also a consideration (Atroshi et al. 1999). Reported CTS symptoms of tingling, pain, and numbness have a prevalence of about 14 per cent, whereas CTS was confirmed in less than 3 per cent.

CTS patients with inflammatory arthritis, diabetes, and hypothyroidism were more likely to receive CTS release surgery (Solomon et al. 1999). Heredity is the single strongest predictor of CTS with half of the risk of CTS due to genetic factors (Hakim et al. 2002). Using MZ and DZ twins, the heritability was estimated to be 0.46 (95 per cent CI 0.34–0.58). There is a bimodal age distribution with peaks at 50–54 and 75–84 years of age (Bland and Rudolfer 2003). In a case-control study, elevated body mass index was more common among cases than among control subjects (Stallings et al. 1997).

Diabetes mellitus

Diabetes is a common, yet complex cause of both mono- and polyneuropathies. Diabetic peripheral neuropathy may affect 26–47 per cent of those with diabetes (Barrett et al. 2007) though others have found lower rates of 7.8–17.4 per cent (Dyck et al. 2012). More effective glucose control could reduce the risk to some extent. The cost of diabetic peripheral neuropathy, particularly in those with pain, can be substantial (Currie et al. 1998; Barrett et al. 2007).

Microvascular disease, chronic hyperglycaemia, and type of diabetes are the most important predictors of polyneuropathy (Dyck et al. 1999). Autonomic neuropathy is strongly influenced by hyperglycaemia and is associated with increased mortality (Orchard et al. 1996). Elevated diastolic blood pressure, ketoacidosis, elevated fasting triglyceride level, and microalbuminuria are also risk factors for diabetic polyneuropathy (Tefaye et al. 1996).

Nutritional neuropathies

Vitamin B₁₂ deficiency is the most common of a number of nutritional deficiencies that can lead to peripheral neuropathy. A Cuban epidemic of peripheral neuropathy from 1992 to 1993 affected over 50,000 people with an incidence of 461 per 100,000 people (Roman 1994). Optic and peripheral forms of the disease were observed. A nutritional deficiency is suspected and treatment with multivitamins, in particular B vitamins, stopped the outbreak.

Peripheral neuropathy due to infection

HIV infection is an important cause of peripheral neuropathies including diffuse peripheral neuropathy, Guillain-Barré syndrome, mononeuropathies, neuropathies due to secondary infections, and neuropathies due to medications (Brew 2003). The incidence and prevalence vary too much between studies to allow accurate estimates.

Guillain-Barré syndrome is due to an autoimmune attack on the peripheral nerve myelin. Previously considered an idiopathic disease, it is now recognized that a significant proportion of cases are associated with prior infections (Hardy et al. 2011). Though the prevalence of leprosy is declining, it remains one of the most important causes of peripheral neuropathy in the developing world (Suzuki et al. 2012). Fortunately, early treatment can prevent many of the disabling and disfiguring effects of the disease.

Parkinsonism and Parkinson's disease

The Parkinson's research community is somewhat fragmented with regard to how idiopathic PD should be described and characterized: a) should full clinical symptomatology (e.g. cardinal signs) be required; b) should evidence of PD pathophysiology (e.g. Lewy body pathology) be sufficient to say PD exists; c) should PD be viewed as a systemic neurodegenerative disorder in contrast to focus on movement disorder (Langston 2006; Litvan et al. 2007)? The argument for expanding the view of PD continues that limiting the clinical and pathological view of the disease itself limits the potential for research progress (Langston 2006).

Clinical overview of PD

There are four cardinal features of clinical PD: tremor, rigidity, bradykinesia, and postural gait changes. The clinical diagnosis of PD usually requires two or more of these symptoms. In severe cases, patients may be unable to move (freezing) when they encounter minor obstacles such as doorways or cracks. While movement disorder specialists make the diagnosis of parkinsonism with some degree of confidence, PD usually requires histopathological confirmation. In an attempt to increase the accuracy and validity of clinical diagnosis, improvements in clinical diagnostic criteria have been proposed (Gelb et al. 1999; Jankovic et al. 2000).

Parkinsonism includes several major subclasses: idiopathic parkinsonism (PD), symptomatic parkinsonism (e.g. drug induced, toxin induced, and other specific causes), 'parkinson-plus' syndromes (e.g. multiple system atrophy (MSA), progressive supranuclear palsy), and hereditary degenerative diseases (e.g. Hallervorden-Spatz disease, Huntington disease). PD or idiopathic parkinsonism comprises approximately 80 per cent of parkinsonism.

MSA is sometimes misdiagnosed as PD; it is a relatively rare and very debilitating condition usually involving progressive autonomic failure plus poor responsiveness to levodopa or cerebellar ataxia. There is new evidence that MSA like PD and DLB is a synucleinopathy (Goedert and Spillantini 1998; Dickson et al. 1999; Armstrong et al. 2006).

Incidence and prevalence of PD

PD prevalence has been reported with dramatic inconsistency; typically prevalence has been reported in the range of about 50 per 100,000 to 200 per 100,000 of the population, with a maximum of about 350 per 100,000 people. Combined results of five European

studies (de Rijk et al. 1997) included 14,636 people age 65 or older; after age adjusting to the European 1991 standard population the prevalence of PD was reported as 1.6 per 100 population (presumably age 65 or older), this translates to about 1600 per 100,000. In addition, the age-specific prevalence of PD was reported to increase from 0.6 per cent in 65–69-year-olds to 3.5 per cent in 85–89-year-olds (or 600 per 100,000 to 3500 per 100,000) (de Rijk et al. 1997).

Incidence rates for PD and parkinsonism carry many of the same caveats as for prevalence. Bower et al. (1999) studied the incidence of parkinsonism and PD in Rochester, Minnesota, United States, 1976–1990. The age-specific incidence for the 50–59 age group was 17.4 per 100,000 person-years, rising to 52.5 for ages 60–69 and peaking at 93.1 for the 70–79 age group and 79.1 for 80–99-year-olds. Parkinsonism showed an overall incidence rate of 25.6 per 100,000 person-years and rose from 26.5 at ages 50–59 to 304.8 per 100,000 person-years in those aged 80–99 (Bower et al. 1999). Age-specific incidence rates are, of course, able to be compared directly whereas summary population rates may be dependent on age structure of the population. How ageing contributes to the clinical expression or degenerative processes of PD, as well as how ageing may act with genetic and environmental risk factors, to initiate pathophysiology or onset of clinical symptoms remain key questions for the epidemiology of parkinsonism and PD.

Risk factors of PD

Researcher hopes to identify consistent environmental causes of PD were increased by the observation that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) caused acute PD shortly after ingestion (Langston and Ballard 1983; Langston et al. 1983). The structure of MPTP and its metabolism products are somewhat similar to common pesticides raising interest in such exposures as risk factors or causes of PD. The past predominance of environmental causes has at least partially given way to studies of genetic and pathophysiological aetiologies (Litvan et al. 2007; Do et al. 2011).

An excellent review of pesticide/herbicide exposure as risk factors for PD was recently published by Tanner et al. (2011). Determination of critical exposure time periods and duration of exposures is always an obstacle to overcome when studying PD risk factors because the initiation of pathophysiology may occur many years prior to any symptoms of the diagnosis of PD. Further, the time from exposure to onset of pathophysiology or clinical disease may vary dramatically. Consider the rather immediate onset of clinical symptoms following MPTP exposure compared with what may be the case with agricultural pesticides (Gorell et al. 1998; Petrovitch et al. 2002; Firestone et al. 2005). Interest in pesticide exposure as a potential cause led to a bio-transformation gene approach for evaluating the occurrence of susceptible people. Specifically, some people may be more, or less, able to metabolize environmental toxins because of polymorphic genes involved in metabolism. One of the family of cytochrome P-450 biotransformation genes, *CYP2D6*, is involved in metabolism of debrisoquine (structurally similar to pesticides); some polymorphic forms are 'poor' metabolizers and others are normal or rapid metabolizers of debrisoquine. Initial studies appeared to show that poor metabolizers were at increased risk of PD but later studies and meta-analyses fail to support this conclusion

(Maraganore et al. 2000; Scordo et al. 2006). A similar approach has been taken to identify susceptibles focusing on polymorphic forms of glutathione transferases (GST) which are involved in the metabolism of pesticides and other xenobiotics (Menegon et al. 1998). Continued effort to identify gene–environment interaction in this way may eventually prove fruitful, but success is rather limited to date.

An association between exposure to metals and PD has been described by Gorell et al. (1999). And more recently an association with welding has been reported by Racette et al. (2012). Heavy metals such as iron, copper, manganese, and lead have been raised as potential risk factors in the past and Racette et al. may provide some measure of replication to those findings.

Smoking has been rather consistently associated with decreased risk of PD in reported reviews and in individual studies. Reasons for the plausibility of such an association revolve around the potential action of nicotine on neurons. Although this is one of the more consistent findings, it is not completely without alternative explanations. Most epidemiological studies of PD use ‘prevalent’ or existing cases in their studies. The low incidence of PD effectively precludes concentrating on only newly diagnosed cases in all but the largest of studies (or in very large cohort studies). When attempting to identify a cross-sectional sample of cases for enrolment into a case–control study, it can be shown that those patients who have had the disease the longest are the most likely to be included. The most severe, short-duration or rapidly declining cases tend to be missed. If PD cases who had a history of smoking were much more likely to die sooner than ‘controls’ who were smokers, then smoking would appear to be protective because of the excess of smoking ‘controls’. Despite such an argument, however, the PD research community appears to be relatively confident in the potential protective effect of smoking (Ritz et al. 2007).

Dietary-related factors have been shown in some studies to affect risk of PD: fish and vegetables (Gao et al. 2007), coffee and caffeine (Ross et al. 2000), dietary folate, and vitamin B₁₂ among others (de Lau et al. 2006). Body mass index has been reported to increase the risk of PD (Hu et al. 2006), while gout and hyperuricaemia has been reported to protect against it (de Lau et al. 2005; Alonso et al. 2007).

As recently as two decades ago it was commonly taught that PD was caused entirely by environmental factors. Now with the explosion of genetic knowledge and technology and an understanding of some of the proteins potentially involved in pathogenesis, Hardy states that nearly half of the disease risk has been explained by genes so far discovered (Hardy 2010). Do et al. (2011) discuss the recent GWAS and genes involved in PD risk. Glucocerebrosidase has been found to be deficient in PD brains and similarly the *GBA* gene is associated with Lewy body disease causing PD and dementia (Tsuang et al. 2012). While the list of genes involved in PD continues to grow, the acknowledged recessive gene causes appear to be *parkin* (*PARK2*), *PINK1* (*PARK6*), and *DJ-1* (*PARK7*). Autosomal dominant and genetic risk factors include *SNCA*, *UCHL1*, *LRRK2*, *GBA*, and *MAPT*. As discussed by Do and others, the list continues to grow as do the parallels with other neurodegenerative diseases such as AD and FTL. D.

Public health impact of PD

PD is progressive and debilitating. While initial treatments with levodopa and similar medications effectively quell most motor

symptoms, their effectiveness begins to subside in about 50 per cent of patients after 3–5 years. To date, there have been no true disease-modifying treatments available and we are only beginning to examine genetic pathways leading to pathogenesis or to drug targets that may modify the disease process prior to onset of symptoms (Siderowf et al. 2012). This aspiration is still a long way off, it appears. With increasing motor problems comes increased healthcare cost and decreased quality of life (de Boer et al. 1999); dementia is now regarded as an almost inevitable consequence of PD, assuming the patient survives long enough, leading to the need for long-term care in many instances. The overlap between PD dementia and DLB is of great interest because of the potential underlying synuclein pathology and therefore the potential genetic relationships as well (Rocca et al. 2007; Tsuang et al. 2012).

Multiple sclerosis

Clinical overview of MS

Although MS is relatively uncommon, it has a great impact on society. The impact of this disease is disproportionately large because it strikes young adults, is expensive to treat, and can cause disability. Only 21 per cent of MS patients have no work limitations and 29 per cent remain in the workforce (Minden et al. 2004). MS has substantial medical costs (Minden et al. 2004; Adelman et al. 2013). Because of lost earnings and increased healthcare costs, MS is the third leading cause of significant disability in the 20–50-year age range (LaRocca et al. 1984).

Clinically, MS is characterized by demyelinating lesions of central nervous system white matter causing motor, sensory, cerebellar, visual, brainstem, autonomic, spinal cord pathways, and other symptoms. These often occur in attacks with complete or partial recovery, with symptoms remaining stable between exacerbations (relapsing/remitting disease) (Lublin and Reingold 1996). Alternatively, symptoms may slowly progress in the absence of exacerbations (primary progressive disease). Relapsing/remitting cases may evolve into secondary progressive disease with a slow worsening of baseline function. When the disease results in death, the immediate cause is usually infectious, secondary to urinary tract involvement or pneumonia.

The length of exacerbations can be shortened by corticosteroids. There are currently nine US Food and Drug Administration-approved medications to slow the disease, with others under review. In addition to disease-modifying therapies, symptomatic treatments are often required. A multitude of new treatments are being tested, giving hope for more effective treatments in the future.

Definition of MS

The current diagnostic criteria are the revised McDonald criteria (Polman et al. 2011). These require two or more episodes of neurological deficit at different times and different locations within the nervous system. MS attacks used to fulfil the criteria must have symptoms typical of those seen with MS and have objective findings on examination or paraclinical tests. The new criteria allow diagnosis by clinical presentation alone, but also allow magnetic resonance imaging (MRI) findings to be used to demonstrate dissemination in time or location. The revised McDonald criteria allow the disease to be diagnosed at an earlier stage than previous criteria.

Case ascertainment of MS

Because of the necessity for neurological expertise and special studies to make reliable diagnoses, reported worldwide prevalence may not be completely comparable, especially where differences in the availability and quality of healthcare exist. This is especially true in light of the highly variable clinical presentation of the disease, and the variable course. The requirement for repeated attacks before a diagnosis is made and the often vague nature of the initial clinical symptoms leads to difficulties in determining exact incidence figures in a timely manner.

Prevalence of MS

MS prevalence is easier to determine than incidence, particularly considering the difficulty in determining the time of disease onset. With the new McDonald criteria, MRI availability, and increasing awareness of the disease, the time from symptom onset until diagnosis is rapidly shortening (Marrie et al. 2005). The reported prevalence of MS varies widely with latitude, from one per 100,000 or less near the equator, to over 150 per 100,000 in some high-latitude areas (Koch-Henriksen and Sorensen 2011). Migrants carry the risk of their geographic residence before their mid teens (Alter et al. 1966a, 1966b). However, prevalence and incidence relative to latitude appears to be rapidly changing, due primarily to an increase in MS in the South (Hernan et al. 1999; Wallin et al. 2004; Pugliatti et al. 2006; Koch-Henriksen and Sorensen 2011). This is less apparent in the southern hemisphere (Cristiano et al. 2012). The levelling of MS rates with latitude may partially reflect improved case ascertainment, but likely also reflects a true increase in MS in areas in which it was previously rare.

Risk factors of MS

Gender

Approximately 75 per cent of people with MS are female. However, in the first half of the twentieth century, males predominated (Kurtzke 2005). Gender rates changed to a female preponderance about mid century and the female/male ratio continues to increase by about 0.85 per cent/year (Orton et al. 2006; Wallin et al. 2012). The disease is less active during pregnancy and more active during the 3 months immediately postpartum (Confavreux et al. 1998; Langer-Gould and Beaber 2013). The changes in MS activity with hormones and pregnancy may be due to alterations in immune system function, but the temporal changes in gender ratios remain unexplained.

Ethnic background of MS

In general, MS occurs with greater frequency in white people, particularly those of northern European ancestry. Other ethnic groups have a lower incidence and prevalence of MS, but this appears to be changing. The relative risk of MS in black compared with white male veterans increased from 0.44 in the Second World War/Korean conflict to 0.67 in Vietnam to 1.16 in the Gulf War (Wallin et al. 2012). During the same time periods the relative risk among black females compared to white males increased from 1.28 to 2.86 to 3.62, catching up to white females with 1.79, 2.99, and 3.54 respectively.

Genetic susceptibility of MS

In Caucasians, some alleles of the HLA complex are associated with MS susceptibility, particularly HLA-DRB1.1501 (Haines

et al. 1996). In addition, other groups of genes that influence the immune response or myelin structure have been investigated (Sadovnick et al. 1991). To date, large GWAS have identified over 60 loci associated with MS, but associations are modest, explaining less than 25 per cent of the heritability of the disease (Hafler et al. 2007; Sawcer et al. 2011; Lin et al. 2012). Nevertheless, these studies confirm the importance of genes related to immune function.

In the Danish twin study, there was concordance for MS in 24 per cent of MZ twins and 3 per cent of dizygotic twins (Hansen et al. 2005). The standardized incidence ratio for MZ twins compared to non-twins was 1.23 and 0.78 for DZ twins. There is also an increased risk of MS in other first-degree relatives of people with MS. In a Danish study, the relative risk of MS in first-degree relatives of people with MS was 7.1 (95 per cent CI 5.8–8.8) (Nielsen et al. 2005). The lifetime risk was calculated to be 2.8 per cent for male and 2.9 per cent for female first-degree relatives. Some have found that the risk of MS is higher in children of MS fathers than MS mothers (odds ratio 1.99, 95 per cent CI 1.05–3.77) (Kantarci et al. 2006). This increased rate of transmission to offspring by a subgroup in which the disease is less common (men) suggests a genetic contribution in which genes are concentrated in men with the disease. However, others have reported that the risk of MS in children whose parents have MS is similar regardless of whether the affected parent was the father or mother (Herrera et al. 2007). A Canadian study found that the age-adjusted risk of MS in siblings was 3.11 per cent (95 per cent CI 2.39–3.83) (Ebers et al. 2004). This group also found an excess of mother–daughter pairs compared to father–son pairs and suggested that epigenetic factors may contribute (Chao et al. 2010). These studies indicate that there is an important genetic contribution to the disease, but environmental factors also play a major role.

Environmental factors of MS

In the presence of inherent susceptibility, some external factors seem to be associated with MS. People with MS have a later age of exposure to common childhood exanthematous diseases, and lower birth orders though not all studies have supported this finding (Bager et al. 2006). There have been reports of clusters of disease, thought to have been related to environmental exposures, but on investigation these supposed clusters have generally not been beyond expected variability.

The strong relationship between MS and latitude has led some to postulate that areas with less sun exposure, and thus lower levels of vitamin D, may be responsible for the disease (Simon et al. 2012). Military recruits with low 25-hydroxyvitamin D (25(OH)D) levels had a subsequent increased risk of MS. Low vitamin D levels are associated with risk of MS in children. The risk of MS is lower in offspring of mothers with increased vitamin D intake. Patients with MS generally have low 25(OH)D levels. A small trial of 25(OH)D supplementation in MS patients found no difference in MRI activity (Stein et al. 2011). Other randomized treatment trials of 25(OH)D are underway.

The relationship between MS prevalence, latitude, migration, and socioeconomic factors has led some to suggest that MS is related to the degree and timing of exposure to various infectious organisms (Fleming and Cook 2006). This hygiene hypothesis states that exposure to infectious agents later in life (due to high levels of hygiene) leads to changes in the immune system that

eventually lead to MS. Epstein–Barr virus (EBV) is associated with MS (Ascherio and Munger 2007; Owens and Bennett 2012). MS is extremely rare in people who have never had EBV. Furthermore, those exposed to EBV later in childhood have a two- to threefold increase in risk relative to those who acquire EBV in early childhood. Antibody titres to EBV are increased in MS, often years before recognition of the disease, but this may reflect a general upregulation of the immune system. Cytomegalovirus appears to be protective in children (Waubant et al. 2011).

Both ever-smokers and current smokers have an increased risk of MS (Jafari and Hintzen 2011). Children exposed to cigarette smoke have a higher risk of developing MS (Mikaeloff et al. 2007). Smoking is associated with increased disability, more MRI activity, and conversion to secondary progressive MS.

Overview of MS

The risk of MS appears to be due to environmental factors acting on genetically predisposed people. Eventually, these factors lead to an immune attack on the central nervous system, resulting in symptoms. The genetic factors are polygenetic. The environmental factors remain uncertain. Immunomodulating treatments have played an important role in slowing the disease, but their benefits are only partial. Much remains to be clarified about the mechanisms of the disease process, and it is hoped that a better knowledge of these mechanisms will lead to improved treatments.

Conclusion

Presenting current and useful research information on a number of neurological conditions is a difficult task. This chapter has attempted to address that challenge for some selected neurological conditions and referencing heavily to current or classic research papers. Conditions such as headache and back pain have substantial public health impact because of the age groups affected, their prevalence, and the lost productivity (or economic loss) related to them. MS, a relatively common neurological disease, can affect individuals in young adulthood, decrease their productivity, and ultimately make them dependent on others. TBI occurring in youth or young adulthood can cause years of extra medical care in addition to lost productivity among those who survive the immediate event. Epilepsy may have onset throughout the life course, it may result from trauma or may be caused by specific genes, among other causes. While there are intractable forms of epilepsy, great strides have been made in seizure control enabling patients to lead relatively full and normal lives. Neurodegenerative diseases, such as PD and AD, rob productivity, functional ability, and independence from older individuals; they also force huge increases in healthcare costs. Without question neurological diseases have substantial public health effects.

Determining the incidence and prevalence for most of the diseases and conditions in this chapter is quite an inexact science. The conditions are often difficult to define and detect in the population and for the most part they are not regarded as ‘reportable’ conditions. Therefore we gain insight as to disease occurrence primarily from limited but (hopefully) well-designed and conducted studies. As mentioned in the introduction to this chapter, the epidemiological study of neurological conditions is a complicated matter. Problems with diagnostic inaccuracy and insidious disease onset influence our ability to observe risk factor associations;

factors related to survival may be mistaken for risk/protective factors.

The recent work of the Human Genome Project and the HapMap Project have greatly influenced technology and have now made possible genome-wide studies that could not have been imagined a decade ago. The contribution of genes that in and of themselves cause disease may be smaller than that of genes which act together with other genes in complex ways or act to metabolize or potentiate environmental exposures. The interaction between gene and environment will be increasingly well studied in the future. Description of gene products and functions may lead to specific drug therapies never before possible. The genetic information presented in this chapter, while relatively current, may become obsolete quickly. The fields of genetics and molecular biology are moving rapidly. It is a challenge also for epidemiologists to apply the knowledge gained by the genetic researchers to the design and analysis of epidemiological studies. The diagnosis of neurological conditions may be made more accurately and earlier with genetic information. Science and the public health will benefit beyond even our current expectations.

Epidemiology must take advantage of these molecular advances. Many scholars have written on pros and cons of reductionism in science. Much of epidemiology lies in its public health context, and the same is likely to be true for genetic influences on neurological diseases. Arrays of genes may identify susceptible individuals; however, those individuals may avoid disease unless met with specific environmental or behavioural exposures. The tasks of public health and epidemiology will still involve prevention, the non-random occurrence of disease, and its environmental context—in addition to heredity. The tools to address those tasks will continue to be refined.

Infectious diseases and prions

Davidson H. Hamer and Zulfiqar A. Bhutta

Introduction to infectious diseases and prions

Infectious diseases are a major cause of morbidity, disability, and mortality worldwide. During the last century, substantial gains have been made in public health interventions for the treatment, prevention, and control of infectious diseases. Nevertheless, recent decades have seen a worldwide pandemic of the human immunodeficiency virus (HIV), increasing antimicrobial resistance, and the emergence of many new viral, bacterial, fungal, and parasitic pathogens.

As a result of changes in a variety of different environmental, social, economic, and public health factors, morbidity and mortality due to infectious diseases have declined in industrialized countries during the last 150 years with the result being a gradual transition to chronic diseases including cardiovascular disease, diabetes mellitus, and cancer as major causes of mortality in these countries today. However, in contrast, in less developed countries, infectious diseases continue to contribute substantially to the overall burden of disease.

Detailed information on the definitions of infectious diseases, modes of transmission, and their control are provided in Chapter 11.3. An overview of issues related to emerging and re-emerging infections is provided in Chapter 8.17. Similarly, detailed information on diseases caused by sexually transmitted infections, HIV/acquired immunodeficiency syndrome (AIDS), tuberculosis, and malaria can be found in Chapters 8.12–8.15. This chapter will review the global burden of common infectious diseases in children and adults, determinants of the high infectious disease burden in resource-poor countries, and important aspects of the clinical manifestations, diagnosis, and treatment of the handful of infectious diseases that account for the major share of morbidity and mortality in children and adults worldwide.

Burden of infectious diseases

At the beginning of the twentieth century, infectious diseases were the leading cause of death throughout the world. At that time, three diseases—pneumonia, diarrhoea, and tuberculosis—were responsible for about 30 per cent of deaths in the United States. During the last century, there has been a decline in infectious diseases mortality in the United States from 797 deaths per 100,000 in 1900 to 36 per 100,000 in 1980. Despite substantial reductions

in all-cause mortality due to diarrhoeal disease and tuberculosis, pneumonia and influenza have continued to be major causes of mortality (Armstrong et al. 1999). Concurrent with the growth of the AIDS pandemic worldwide, there was a rise in mortality rates among persons aged 25 years and older in developed and less developed areas of the world.

In the late twentieth century, substantial reduction in child mortality occurred in low- and middle-income countries. The fall in the number of child deaths from 1960 to 1990 averaged 2.5 per cent per year and the risk of dying in the first 5 years of life halved—a major achievement in child survival. In the period from 1990 to 2001, mortality rates dropped an average of 1.1 per cent annually, mostly after the neonatal period. Deaths among children under 5 years of age dropped from nearly 12 million in 1990 to about 6.9 million in 2011. The Countdown to 2015, a multi-stakeholder group tracking progress towards the Millennium Development Goals in the 75 countries which have almost 98 per cent of the burden of maternal and child mortality, estimates that 30 countries have cut child mortality rates by half or more from 1990 to 2011, and two-thirds of the 75 Countdown countries have accelerated their progress since 2000 compared with the previous decade.

Newborn deaths, that is, deaths within the first month of life, now account for more than 40 per cent of child deaths in 35 Countdown countries, and 50 per cent or more in 12 countries. As deaths in children under the age of 5 have decreased, the proportion of these deaths that occur during the newborn period has increased. At the same time, the rate of progress in reducing newborn deaths has been far slower compared with the rate of progress in reducing deaths of older children. There has been considerable progress in the categorization and estimates for under-5 mortality through the work of the Interagency Group for child Mortality Estimation (IGME), the Child Health and Epidemiology Reference Group (CHERG), the Institute for Health Metrics and Evaluation (IHME), and the Countdown for 2015.

Neonatal causes, diarrhoea, pneumonia, and malaria account for the bulk of child deaths globally with regional variations (Liu et al. 2012). The recent distribution of these major causes of mortality in various World Health Organization (WHO) regions is presented in Fig. 8.11.1.

The South East Asian region accounts for the highest number of child deaths, over 3 million, whereas the highest mortality rates are generally seen in sub-Saharan Africa. Annually, sub-Saharan

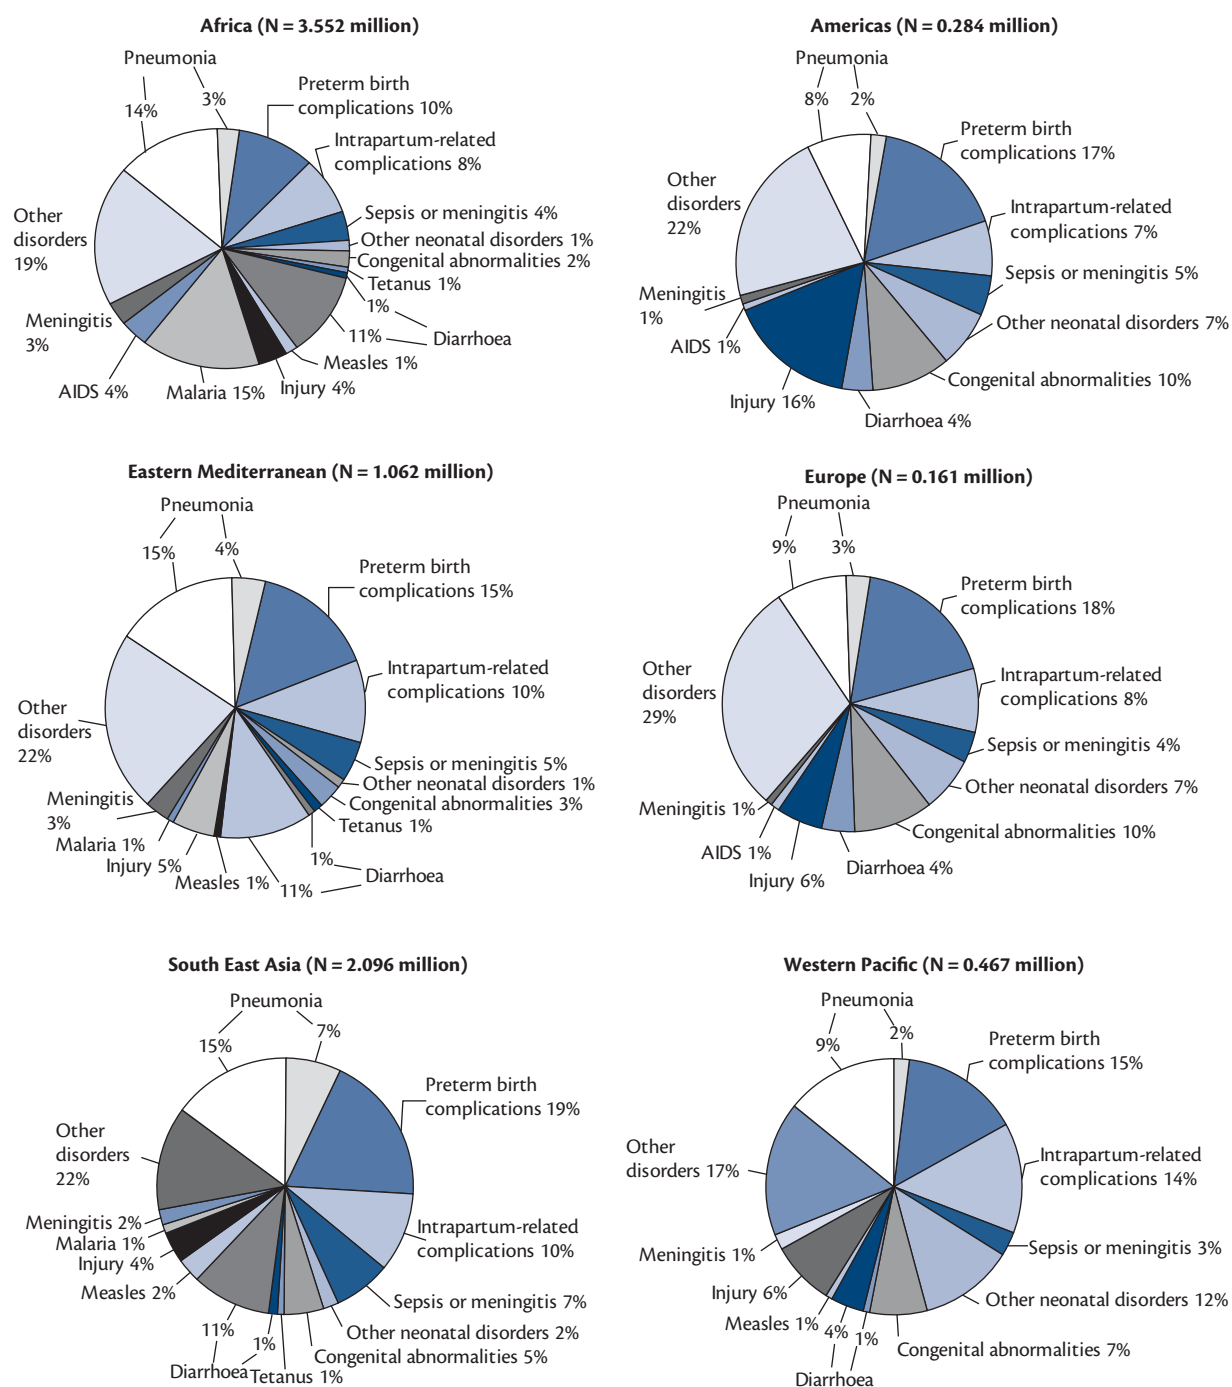

Fig. 8.11.1 Regional causes of child mortality 2010.

Reprinted from *The Lancet*, Volume 379, Issue 9832, Liu L. et al., Global, regional, and national causes of child mortality: an updated systematic analysis for 2010 with time trends since 2000, pp. 2151–61, Copyright © 2012, with permission from Elsevier, available from <http://www.sciencedirect.com/science/journal/01406736>.

Africa and South Asia share 41 and 34 per cent of child deaths respectively (Black et al. 2003). Only six countries account for half of worldwide deaths and 42 for 90 per cent of child deaths with the predominant causes being pneumonia, diarrhoea, and neonatal disorders, with surprisingly little contribution from malaria and AIDS (Table 8.11.1). Estimates from the 2010 Global Burden of Disease study (GBD 2010); (IHME n.d.), including a larger proportion of vital registration data, also suggested broadly comparable

figures for under-5 deaths, although some categories are clearly different, notably a higher proportion of malaria deaths among under-5 children in the GBD 2010 estimates and lower numbers for pneumonia deaths (Lozano et al. 2012).

In all, 99 per cent of neonatal deaths occur in poor countries (estimated average neonatal mortality rate (NMR) of 33/1000 live births) with the remaining divided among 39 high-income countries (estimated average NMR of 4/1000 live births) (Table 8.11.2).

Table 8.11.1 Global deaths for infectious diseases in 1990 and 2010 for all ages and both sexes combined (thousands) and age-standardized rates (per 100,000) with 95% UI and percentage change

	All ages deaths (thousands)			Age-standardized death rates (per 100,000)		
	1990	2010	%Δ	1990	2010	%Δ

Other neglected tropical diseases	22.9 (14.3–29.5)	23.7 (16.6–30.9)	3.4%	0.5 (0.3–0.6)	0.3 (0.2–0.5)	–23.6

Data are deaths (95% uncertainty interval) or % change. %Δ, percentage change; NTDs, neglected tropical diseases.

Adapted from *The Lancet*, Volume 380, Issue 9859, Lozano, R. et al., Global and regional mortality from 235 causes of death for 20 age groups in 1990 and 2010: a systematic analysis for the Global Burden of Disease Study 2010, pp. 2095–128, Copyright © 2012, with permission from Elsevier, available from <http://www.sciencedirect.com/science/journal/01406736>.

As of the end of 2012, the Joint United Nations Programme on HIV/AIDS (UNAIDS) estimated that there were 34 million people living with HIV infection in 2011 (range 31.4–35.9 million) and that 2.5 million new infections occurred during 2011 along with 1.7 million deaths due to AIDS. With around 69 per cent of all people living with HIV residing in sub-Saharan Africa, the region carries the greatest burden of the epidemic. Epidemics in Asia have remained relatively stable and are still largely concentrated among high-risk groups. Conversely, the number of people living with HIV in Eastern Europe and Central Asia has more than

tripled since 2000. Sadly, tuberculosis is responsible for approximately 10 per cent of HIV-associated deaths of children and adults in sub-Saharan Africa, despite substantial increases in the numbers of HIV-infected people receiving antiretroviral therapy.

Lower respiratory tract infections are the second leading cause of disability-adjusted life years (DALYs) worldwide, accounting for 4.6 per cent of the total, and diarrhoea is fourth, accounting for 3.6 per cent (Murray et al. 2012). HIV/AIDS is fifth on the list accounting for 3.3 per cent, while malaria and tuberculosis rank seventh and thirteenth, accounting for 3.3 and 2.0 per cent of

Table 8.11.2 Estimated numbers of deaths by cause in 2010

	Estimated number (millions)
Neonates aged 0–27 days	
Preterm birth complications	1.078 (0.916–1.325)
Intrapartum-related complications	0.717 (0.610–0.876)

Uncertainty range (UR) is defined as the 2.5–97.5 percentile. Other disorders in children aged 1–59 months included congenital abnormalities, causes originated during the perinatal period, cancer, pertussis, severe malnutrition, and other specified causes. Intrapartum-related complications were formerly referred to as birth asphyxia.

^a The estimated number of deaths in children younger than 5 years overall is 1.396 million (UR 1.189–1.642 million).

^b The estimated number of deaths in children younger than 5 years overall is 0.801 million (UR 0.555–1.182 million).

DALYs, respectively. In high-income countries, lower respiratory infections remain a leading cause of death. No communicable disease is among the top ten leading causes of DALYs in high-income countries. In contrast, pneumonia, HIV/AIDS, diarrhoea, and malaria rank among the top ten causes of death and DALYs in low- and middle-income countries.

Factors responsible for the decline in infectious diseases in industrialized nations during the last century include improved nutrition, safer food and water supplies, improved hygiene and sanitation, the introduction of antimicrobial agents, and immunizations, all of which resulted in decreased host susceptibility and reductions in disease transmission (Cohen 2000). While there have been substantial reductions in morbidity and mortality due to communicable diseases in the last century, there remain significant gaps in child and adult mortality between rich and poor countries.

Apart from the immediate causes of infections in childhood, a number of determinants contribute to the high burden of infectious diseases in developing countries. These include several distal

determinants such as income, social status, and education, which work through an intermediate level of environmental and behavioural risk factors. These risk factors, in turn, lead to the proximal causes of death (nearer in time to the terminal event), such as undernutrition, infectious diseases, and injury (Rice et al. 2000). The major social determinants affecting the mortality and morbidity of young children include poverty, crowding, poor housing conditions, indoor air pollution, malnutrition, inequity, lack of education, failure to implement breastfeeding and complementary feeding programmes, the presence of debilitating disease in addition to infections, complications of labour and low birth weight (LBW), inadequate health-related social behaviours and practices, and other social and cultural determinants of health.

Specific disease categories

As described in the previous section, a limited number of infectious diseases are responsible for a large proportion of the total global burden of morbidity and mortality, especially in resource-limited areas of the world. This section will provide an overview of the major types of infectious diseases responsible for the bulk of acute and chronic morbidity and mortality of children and adults worldwide. Detailed information on approaches for the prevention and control of these diseases is available in Chapter 11.3.

Acute respiratory infections

Acute respiratory infections (ARIs) are classified as upper or lower respiratory tract infections. Upper respiratory tract infections include the common cold, otitis media, sinusitis, and pharyngitis while lower respiratory tract infections include laryngitis, tracheitis, bronchitis, bronchiolitis, pneumonia, and any combination thereof. ARIs are not only confined to the respiratory tract, but may also have systemic effects due to extension of infection into the bloodstream, the production of microbial toxins, inflammation, and reduced lung function.

ARIs, especially bronchiolitis and pneumonia, are the most common causes of both illness and mortality in children under 5 years. In adults, pneumonia and influenza are major causes of morbidity and mortality in developed as well as less-developed nations.

Global and regional epidemiology

The annual incidence in children in Europe and North America is 34–40 cases per 1000, higher than at any other time of life, except perhaps in adults older than 75 or 80 years of age. For example, in the United States, there are about 4 million adults who develop pneumonia each year, of whom greater than 1 million are hospitalized.

Pneumonia is the most severe and largest killer of children, causing almost 20 per cent of all child deaths globally. Recent estimates indicate that there are approximately 1.4 million pneumonia deaths annually, with 75 per cent of all childhood pneumonia cases occurring in just 15 countries (Liu et al. 2012). There was a decrease in pneumonia deaths of about 0.45 million between 2000 and 2010.

Most ARI deaths are due to pneumonia. The annual incidence of pneumonia is estimated at 156 million new cases per year, of which 11–20 million (7–13 per cent) cases are severe enough to require hospitalization. Serious neonatal infections account for

30–50 per cent of neonatal mortality in different regions, and it is difficult to disentangle sepsis and deaths from pneumonia. With the inclusion of neonatal pneumonia, recent estimates indicate that pneumonia is the single largest contributor to child mortality, accounting for about 18 per cent of all under-5 deaths globally. It is also important to note that in contrast to diarrhoeal deaths where mortality rates have declined dramatically, despite the introduction of a global programme for the control of ARIs almost 15 years ago, there has been only a small reduction in the overall burden of pneumonia deaths. A recent assessment of the global burden of severe pneumonia estimated that in 2010 some 11.9 million (95 per cent confidence interval (CI) 10.3–13.9 million) episodes of severe and 3.0 million (2.1–4.2 million) episodes of very severe acute lower respiratory infections (ALRIs) resulted in hospital admissions in young children worldwide (Nair et al. 2011). Incidence was higher in boys than in girls, the sex disparity being greatest in South Asian studies. Using data from 37 hospital studies reporting case fatality ratios for severe ALRI, we estimated that roughly 265,000 (95 per cent CI 160,000–450,000) in-hospital deaths took place in young children, with 99 per cent of these deaths in developing countries. Therefore, the data suggest that although 62 per cent of children with severe ALRI were treated in hospitals, 81 per cent of deaths probably took place at home.

In terms of the overall burden of disease, upper and lower ARIs account for a major proportion of outpatient visits, antibiotic prescriptions, and healthcare costs in the United States and Western Europe. Despite gains in the availability and quality of healthcare in industrialized countries, ARIs, especially lower respiratory tract infections, remain a major cause of morbidity and mortality for adults and children. In fact, even today pneumonia and influenza together are the sixth most common cause for death among adults in the United States. Recovery from pneumonia in the elderly takes longer and complications and mortality are also more frequent than in younger populations. Pneumonia is one of the most common causes of hospitalization and decreased activities of daily living among the elderly. Risk factors for death from pneumonia in adults include advanced age, alcohol consumption, leucopenia, bacteraemia, hypoxaemia, co-morbid conditions such as diabetes mellitus, congestive heart failure, active malignancies, and immunosuppression, and certain signs and symptoms including hypothermia, hyperthermia, tachypnoea, hypotension, and altered mental status. In addition, post-obstructive pneumonia,

aspiration pneumonia, and infections due to *Staphylococcus aureus* and Gram-negative bacilli are independently associated with increased mortality risk.

Many factors such as the presence of certain co-morbid medical conditions, use of certain drugs, changes in physiochemical characteristics of the non-specific host defence system such as cilia and mucus of the respiratory tract, malnutrition, and mechanical devices contribute to an increased incidence of pneumonia among the elderly. However, an important predisposing factor to the increased incidence of infections is the age-associated decline in immune responsiveness. Changes in immune response not only decrease resistance to pathogens but also contribute to increased morbidity and mortality due to respiratory infections.

Aetiology

A wide range of different bacterial and viral pathogens is responsible for community-acquired pneumonia in children and adults. Foremost among them is *Streptococcus pneumoniae*, which accounts for up to half of all cases. Other commonly encountered bacterial pathogens include *Haemophilus influenzae*, *Chlamydia pneumoniae*, *Moraxella catarrhalis*, *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Staphylococcus aureus*, and Gram-negative rods such as *Klebsiella pneumoniae* and *Escherichia coli* (Table 8.11.3). During recent years, the role of viral pathogens in the aetiology of ALRIs has been increasingly described. While influenza is well recognized as a cause of viral pneumonia, several studies have demonstrated the importance of parainfluenza virus, respiratory syncytial virus (RSV), adenovirus, and human metapneumovirus.

Issues in presentation and diagnosis

Currently, the standard WHO algorithm for ARIs defines non-severe pneumonia as cough or difficult and fast breathing (respiratory rate of 50 breaths per minute or more for children aged 2–11 months; or respiratory rate of 40 breaths per minute or more for children aged 12–59 months) and either documented fever of above 101°F or chest in-drawing. Severe pneumonia is defined as having cough or difficult breathing, with tachypnoea and in-drawing of the lower chest wall (with or without fast breathing); and very severe pneumonia—cough or difficult breathing with one or more danger signs (central cyanosis, inability to drink, or unusually sleepy). The WHO has defined pneumonia solely on

Table 8.11.3 Pathogen-specific causes of childhood and adult pneumonia

Age range	Most common causative organism
Neonates (from birth to 30 days after birth)	<i>Streptococcus pyogenes</i> , <i>Staphylococcus aureus</i> , and <i>Escherichia coli</i>
Infants (from 3 weeks to 4 months)	<i>S. pneumoniae</i>
Infants older than 4 months and preschool-aged children	Respiratory viruses and <i>S. pneumoniae</i>
Children in developing countries	<i>S. aureus</i> and <i>Haemophilus influenzae</i> including non-typable strains
Adults—outpatient	<i>S. pneumoniae</i> , <i>Mycoplasma pneumoniae</i> , <i>H. influenzae</i> , <i>Chlamydia pneumoniae</i> , and respiratory viruses
Adults—inpatient	<i>S. pneumoniae</i> , <i>M. pneumoniae</i> , <i>C. pneumoniae</i> , <i>H. influenzae</i> , <i>Legionella pneumophila</i> , respiratory viruses, and aspiration
Adults—intensive care unit	<i>S. pneumoniae</i> , <i>S. aureus</i> , <i>L. pneumophila</i> , Gram-negative bacilli, and <i>H. influenzae</i>

the basis of clinical findings obtained by visual inspection and setting respiratory rate cut-offs. It is recognized that mortality in children due to ARIs could be reduced by one-half if early detection and appropriate treatment could be provided.

In contrast to the simple, clinical definition of pneumonia recommended by the WHO for use in developing countries, pneumonia in resource-rich countries is usually based on the presence of characteristic signs and symptoms (e.g. dry or productive cough, tachypnoea, fever, focal findings on respiratory examination), hypoxaemia, and the presence of infiltrates on chest radiograph. In general, the elderly tend to present with fewer or atypical symptoms of pneumonia than younger patients and therefore non-specific features such as fever or mental status change may be indicators of an underlying lower respiratory tract infection.

Microbiological studies can be pursued to support the diagnosis of pneumonia due to specific infectious agents and to facilitate decision-making for antibiotic management. While broad-spectrum empirical antimicrobial coverage is recommended in various guidelines, there is a potential risk for clinical failure and increased mortality if inappropriate antibiotic therapy is initiated. If available and adequate quality specimens can be obtained, blood cultures and sputum Gram stain and culture should be performed. Rapid diagnostic tests may be useful when specific diagnoses are being considered such as RSV, influenza, or *L. pneumophila*.

Clinical approaches for the management of childhood pneumonia are significantly hampered by the lack of a gold standard, as classic microbiological methods have poor sensitivity and current algorithms lack sufficient specificity. It is therefore likely that community strategies for the recognition and management of pneumonia by ancillary health workers that rely on simple clinical criteria, other than auscultation, will overdiagnose bacterial pneumonia. There are legitimate concerns that widespread use of first-line antibiotics for all ARIs will lead to loss of effectiveness.

Evidence-based interventions

Only in the early 1980s, long after immunization and diarrhoea control programmes were launched, did the international community become aware of the epidemiological magnitude of pneumonia in children. This need for action led the WHO and the United Nations Children's Fund (UNICEF) to decide that reduction of mortality from pneumonia should be the main objective of the initial ARI programme. Since early microbiological studies of lung aspirates taken from hospitalized, untreated children with pneumonia in developing countries showed that bacteria were present in more than 50 per cent of cases and it was recognized that bacterial pathogens were responsible for the most severe cases, it became apparent that prompt treatment with a full course of effective antibiotics could be life-saving.

Antibiotic treatment of pneumonia

Although recommendations for antibiotic therapy for pneumonia are based on aetiological diagnosis, identification of the causative organism in routine clinical care is very difficult and empirical antibiotic therapy is often instituted. Guidelines for the treatment of pneumonia in immunocompetent adults in industrialized nations generally recommend a macrolide or doxycycline for outpatients; an advanced macrolide such as azithromycin or clarithromycin plus a beta-lactam or a respiratory fluoroquinolone alone for less acutely ill inpatients; and a beta-lactam plus either an advanced macrolide or respiratory fluoroquinolone for adults requiring intensive care (Mandell et al. 2007).

The various modalities for antibiotic treatment in children according to disease severity are shown in Table 8.11.4.

The current WHO treatment guidelines for ARIs were developed before the rise of HIV infection in sub-Saharan Africa, and they do not include empiric treatment for *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia. Daily administration of co-trimoxazole is

Table 8.11.4 Treatment of paediatric pneumonia according to disease severity

Signs/symptoms	Classification	Treatment
Fast breathing: ≥ 60 breaths/min in child aged < 2 months ≥ 50 breaths/min in child aged 2–11 months ≥ 40 breaths/min in child aged 1–5 years	Pneumonia	Home care
		Give appropriate antibiotics for 5 days
Definite crackles on auscultations		Soothe the throat and relieve the cough with a safe remedy
		Advise the mother when to return immediately
		Follow up in 2 days
Signs of pneumonia plus chest wall in-drawing	Severe pneumonia	Admit to hospital
		Give recommended antibiotics
		Manage airway
		Treat high fever if present
Signs of severe pneumonia plus central cyanosis, severe respiratory distress, and inability to drink	Very severe pneumonia	Admit to hospital
		Give the recommended antibiotics
		Give oxygen
		Manage airway
		Antipyretics

advocated since it reduces deaths from opportunistic infections in symptomatic HIV-infected children, including pneumonia caused by *P. jirovecii*. A multicentre randomized control trial, by the APPIS Group, showed that standard empiric therapy for severe pneumonia with injectable penicillin or oral amoxicillin in severe pneumonia in infants is inadequate where HIV prevalence is high (Addo-Yobo et al. 2004). There is also concern that the current diagnostic criteria for non-severe pneumonia may be picking up non-bacterial infections as antibiotic therapy has been shown to add little in terms of improved outcomes compared to placebo. However, management of severe pneumonia in community settings by CHWs using oral amoxicillin has been shown to be both feasible and associated with improved outcomes (Bari et al. 2011; Soofi et al. 2012a). This has major implications for saving lives of children with pneumonia in difficult circumstances where referral may not be possible.

The benefits of the WHO guidelines would be enhanced if they could also be applied (with modification) throughout areas with high rates of HIV infection and where the pneumonia burden is high, even in HIV-negative children.

Integrated management of childhood infections

In the mid 1980s, the WHO initiated a control programme for ARIs that focused on cases managed by health workers. The current case management of ARIs has been incorporated into the global integrated management of childhood infections (IMCI) which train health workers to recognize fast breathing, lower chest wall in-drawing, or danger signs in children with respiratory symptoms (such as cyanosis or inability to drink).

Preventive measures

Poverty, overcrowding, air pollution, malnutrition, harmful traditional practices, and delayed and inappropriate case management are important underlying determinants for high ARI case fatality rates. Preventive strategies for pneumonia include immunizing children with the pneumococcal, measles, and *H. influenzae* type b (Hib) vaccines, hand washing, reduction of the incidence of LBW, ensuring warmth after birth and appropriate feeding, promoting adequate nutrition (including exclusive breastfeeding and zinc intake), and reducing indoor air pollution (Bhutta 2007).

Three vaccines have the potential to substantially reduce deaths in children under 5 years of age—the Hib, measles, and pneumococcal vaccines. Two kinds of vaccines are currently available against pneumococci: a 23-valent polysaccharide vaccine (23-PSV), which is more appropriate for adults than children, and several different formulations of protein-conjugated polysaccharide vaccines (PCV), which contain 7, 10, and 13 serotypes of *S. pneumoniae*. Rates of invasive pneumococcal disease (IPD) have decreased among immunized children and non-immunized adults since the introduction of the heptavalent PCV for use in infants in the United States in 2000. Moreover, newer versions of the PCV have the potential to significantly reduce pneumonia deaths in developing countries. While the Hib vaccine is now being used in many resource-poor countries, scaling up of the PCV lags behind.

Controlled trials of hand washing promotion in child-care centres in developed countries have reported significant reduction (12–32 per cent) in rates of upper respiratory tract infections.

A community-based cluster randomized trial of hand washing promotion from Pakistan also reported that frequent hand washing (with or without soap) led to a 50 per cent reduction in pneumonia incidence and a 36 per cent lower incidence of impetigo.

About 3 billion people still rely on solid fuels, 2.4 billion on biomass, and the rest on coal, mostly in China. Globally, there is marked regional variation in solid fuel use in relation to poverty with use rates of less than 20 per cent in Europe and Central Asia and greater than 80 per cent in sub-Saharan Africa and South Asia, intricately linking to poverty. More than half of all the deaths and 83 per cent of DALYs lost attributable to solid fuel use occur as a result of lower respiratory tract infection (pneumonia) in children under 5 years of age and a systematic review of the evidence for the impact of indoor air pollution on a wide range of health outcomes including pneumonia indicates substantial benefits on pneumonia prevention.

Previously, a meta-analysis of trials of daily preventive zinc supplementation showed a significant impact on pneumonia incidence (Zinc Investigators' Collaborative Group 1999). An update of this meta-analysis reaffirms the impact on reduction in the risk of respiratory tract infections (by 8 per cent, respectively) but not on duration of disease (Aggarwal 2007).

Public health implications

Despite the introduction of a global programme for the control of ARIs almost 15 years ago, there have been limited reductions in the overall burden of deaths from pneumonia. The bulk of deaths from childhood pneumonia disproportionately affect the poor who have higher exposure rates to risk factors for developing ARIs, such as overcrowding, poor environmental conditions, malnutrition, and also limited access to curative health services. The importance of reaching the poor with pneumonia in community settings must be underscored. Such strategies involve recognizing and ambulatory management of pneumonia in community settings through community health workers, assuring transportation and access to facilities for severe pneumonia and availability of antibiotics.

Neonatal sepsis

Sepsis and meningitis are significant causes of morbidity and mortality in newborns, particularly in preterm, LBW infants. Serious infections among newborns are estimated to cause 30–40 per cent of neonatal deaths, especially in rural populations. Neonatal sepsis may be defined using clinical criteria (Table 8.11.5) and/or microbiological testing, by positive blood and/or cerebrospinal fluid (CSF) cultures. It may also be classified according to the time of disease onset: early onset (EOS) and late onset (LOS). Meningitis can occur as a part of sepsis in both the EOS and LOS time periods or as focal infection with LOS disease. The distinction has clinical relevance, as EOS disease is mainly due to bacteria acquired before and during delivery, and LOS disease to bacteria acquired after delivery (nosocomial or community sources). In the literature, however, there is little consensus as to what age limits apply, with EOS ranging from 48 hours to 6 days after delivery.

Global and regional epidemiology

The Child Health Epidemiology Reference Group (CHERG) estimated that 40.3 per cent (3.072 million) of 7.6 million under-5 deaths in 2010 occurred in neonates. Among newborn deaths,

Table 8.11.5 Clinical criteria for diagnosis of neonatal sepsis and meningitis^a

Sepsis	Meningitis
<i>Symptoms</i>	<i>General signs</i>
Convulsions	Drowsiness
Inability to feed	Reduced feeding
Unconsciousness	Unconsciousness
Lethargy	Lethargy
Fever (> 37.7°C or feels hot)	High-pitched cry
Hypothermia (< 35.5°C or feels cold)	Apnoea
<i>Signs</i>	<i>Specific signs</i>
Severe chest in-drawing	Convulsions
Reduced movement	Bulging fontanelle
Crepitations	
Cyanosis	

^a The more symptoms a neonate has, the higher the probability of the disease.

major causes included preterm birth complications (14.1 per cent; 1.078 million, uncertainty range (UR) 0.916–1.325), intrapartum-related complications, previously labelled as birth asphyxia, accounted for 0.717 million deaths (9.4 per cent, UR 0.610–0.876), whereas sepsis or meningitis accounted for 0.393 million (5.4 per cent, UR 0.252–0.552) neonatal deaths. The reported incidence of neonatal sepsis varies from 7.1 to 38 per 1000 live births in Asia, from 6.5 to 23 per 1000 live births in Africa, from 3.5 to 8.9 per 1000 live births in South America and the Caribbean, and from 6–9 per 1000 live births in the United States and Australia. The incidence of neonatal meningitis is 0.1–0.4/1000 live births and is higher in developing countries. Despite major advancement in neonatal care, overall case-fatality rates from sepsis range from 2 to as high as 50 per cent.

Unfortunately, hospitals in developing countries are also hot beds of infection transmission, especially multidrug-resistant nosocomial infections. Reported rates of neonatal sepsis vary from 6.5 to 38 per 1000 live hospital-born babies and the rates of bloodstream infection range from 1.7 to 33 per 1000 live births, with rates in Africa clustering around 20 and in South Asia around 15 per 1000 live births. Factors responsible for hospital-acquired neonatal sepsis include lack of aseptic technique for procedures, inadequate hand hygiene and glove use, deficient sterilization and disinfection practices, overuse of invasive devices, re-use of disposable supplies without adequate sterilization, re-use of single-use vials, overcrowded and understaffed labour and delivery rooms, unhygienic bathing and skin care, contaminated bottle feedings, inappropriate and prolonged use of antibiotics, and lack of effective infection control practices.

Aetiology

In general, Gram-negative pathogens are responsible for a substantial proportion of EOS. In contrast to industrialized countries where group B streptococci (GBS) are common causes of neonatal sepsis, *Klebsiella pneumoniae* is an important aetiology in developing countries. LOS is most commonly due to *E. coli*, *S. aureus*,

S. pyogenes, *S. pneumoniae*, and *Salmonella* spp. The organisms causing neonatal sepsis and meningitis in low and middle income countries are listed in Table 8.11.6.

Evidence-based interventions to address neonatal infections

Child survival and safe motherhood strategies have yet to adequately address mortality in the neonatal period. The fourth Millennium Development Goal (MDG 4) commits the international community to reducing mortality in children aged under 5 years by two-thirds from 1990 base figures by 2015. Real progress in saving newborns will depend upon provision of a good mix of preventive and therapeutic services.

Medical treatment

Reaching and treating sick newborn infants promptly is critical to survival. Normally, health workers use a combination of ampicillin and gentamicin for suspected cases of neonatal sepsis (Table 8.11.7). However, increasing antibiotic resistance among common organisms causing neonatal sepsis in both community and hospital settings presents a challenge to the selection of appropriate antibiotics. Case management of neonatal infections is mainly provided through child-health services, both in facilities and through family-community care. Scaling up of emergency obstetric care and sick neonatal care can be combined. Guidelines for integrated management of pregnancy and childbirth identify opportunities for assimilating maternal and neonatal care. Similarly IMCI has been widely implemented as the main approach for addressing child health in health systems. However, IMCI management guidelines rely on the sick child being brought to a health facility. The recent modification of IMCI to include the neonatal period (IMNCI) and expansion to community settings has now been included as a public health strategy in many countries including India. The ideal strategy would be to provide a linked strategy of care in community settings with referral to facilities in case of need or if needed, antibiotic therapy in first-level facilities.

Following the demonstration of significant reduction in neonatal mortality with the use of oral co-trimoxazole and injectable gentamicin by community health workers, this strategy could be employed in circumstances where referral is difficult. Currently in some health systems, outreach health workers, community nutrition, and child development workers are being trained to visit all mothers and neonates at home two to three times within the first 10 days, starting soon after birth, to provide home-based preventive care/health promotion and to detect neonates with sickness requiring referral. Extra contacts are proposed for LBW babies. With slight modifications, these visits can also be used to provide postpartum care to the mother.

Preventive measures

Preventive interventions need to bridge the continuum of care from pregnancy, through childbirth and the neonatal period, and beyond. Lack of positive health-related behaviour, education, and poverty are underlying causes of many neonatal deaths, either through increasing the prevalence of risk factors such as maternal infection or by reducing access to effective care.

Attempts to reduce the proportion of LBW births at the population level have had limited success. Many deaths in preterm babies and in those born at term with LBW can be prevented with

Table 8.11.6 Distribution of all isolates by age of onset

Organism isolated	N	< 7 days of life % (95% CI)	N	8–59 days of life % (95% CI)	N	60–90 days of life % (95% CI)

extra attention to warmth, feeding, and prevention or early treatment of infections. In developing countries, 90 per cent of mothers deliver babies at home without a skilled health professional present. Simple low-cost interventions, notably tetanus toxoid vaccination, provision of clean delivery kits, exclusive breastfeeding, counselling for birth preparedness, and breastfeeding promotion through peer counsellors and women's groups, have been shown to reduce newborn morbidity and mortality (Darmstadt et al. 2005; Seward et al. 2012). Postnatally, kangaroo mother care for LBW infants, hand washing and decreased congestion in facilities, attention to environmental hygiene and sterilization, and antibiotics for neonatal infections, are additional health system measures. Alcohol-based antiseptics for hand hygiene are an appealing innovation because of their efficacy in reducing hand contamination and their ease of use, especially when sinks and supplies for hand-washing are limited. Creation of a 'step-down' neonatal care unit for very LBW

babies with mothers providing primary care also led to early discharge and reduction in hospital-acquired infection rates in another nursery in Pakistan. These interventions can be delivered through facility-based services, population outreach, and family-community strategies.

Early initiation of breastfeeding affects neonatal health outcomes through several mechanisms. Mothers who suckle their offspring shortly after birth have a greater chance of successfully establishing and sustaining breastfeeding throughout infancy, and also provide a variety of immune and non-immune components that accelerate intestinal maturation, resistance to infection, and epithelial recovery from infection. Prelacteal feeding with non-human milk antigens may disrupt normal physiological gut priming. Although the WHO currently recommends dry cord care for newborns, application of antiseptics such as chlorhexidine has been shown to be effective against both Gram-positive and Gram-negative bacteria and, in

Table 8.11.7 Antimicrobial therapy of neonatal meningitis and sepsis

Patient group	Likely aetiology	Antimicrobial choice	
		Developed countries	Developing countries
Sepsis			
Immunocompetent children	Developed countries: Group B streptococci, <i>E. coli</i> Developing countries: <i>Klebsiella</i> spp. <i>Pseudomonas</i> spp. <i>Salmonella</i> spp.	Ampicillin or penicillin plus an aminoglycoside	Ampicillin or penicillin plus gentamicin Or co-trimoxazole plus gentamicin
Meningitis			
Immunocompetent children (age < 3 months)	Developed countries: Group B streptococci <i>E. coli</i> <i>L. monocytogenes</i> Developing countries: <i>S. pneumoniae</i> <i>E. coli</i>	Ampicillin plus ceftriaxone or cefotaxime	Ampicillin plus gentamicin
Immunodeficient	Gram-negative bacilli <i>L. monocytogenes</i>	Ampicillin plus ceftazidime	

community studies, to reduce rates of cord infection and sepsis in newborns. Recent community-based studies evaluating the role of cord application of 4 per cent chlorhexidine suggest that this could be a very useful strategy to prevent neonatal sepsis in circumstances with high risk of infections (Mullany et al. 2006; Arifeen et al. 2012; Soofi et al. 2012b). A closely related issue is the need for general skin care. A randomized controlled trial of topical application of sunflower seed oil to preterm infants in an Egyptian neonatal intensive care unit showed that treated infants had substantially improved skin condition and half the risk of LOS infection (Darmstadt et al. 2004).

At least two doses of tetanus toxoid should be given during pregnancy so that protective antibodies can be transferred to the fetus, to protect it from neonatal tetanus. Women with a history of prolonged rupture of membranes, especially if preterm, should be given prophylactic antibiotics. This approach improves neonatal outcome by increasing the latency of pregnancy. Maternal antibiotic therapy in this situation is effective in prolonging pregnancy and reducing maternal and neonatal infection-related morbidities. A multicountry study (ORACLE I) from urban centres suggested that administration of erythromycin to women with preterm premature rupture of membranes (PPROM) was associated with significant health benefits for the newborn. A domiciliary cadre of trained birth attendants potentially can be trained to recognize PPRM and provide referral and, possibly, initial antimicrobial therapy.

An important aspect of prevention of neonatal infection in developed countries relates to GBS disease. The joint guidelines developed and implemented in the United States have led to a significant reduction in the burden of disease. The majority of newborns born to mothers with risk of GBS colonization undergo a full diagnostic evaluation and empiric therapy.

In recent years, the importance of hospital-acquired infections in newborn infants, frequently with multiresistant organisms, has been recognized. It is imperative that preventive strategies such as hand washing, reducing overcrowding and congestion, and environmental control are strictly enforced. Strategies to rotate antibiotics, reduce unnecessary hospital stay, strengthen infection prevention practices, and strict hand washing are critical to address this growing problem.

Meningitis in neonates, children, and adults

Acute meningitis is a potentially fatal infection caused by several microorganisms including bacteria, viruses, parasites, and fungi. In addition, meningitis is associated with a risk of chronic morbidity and developmental disability. Although the exact incidence of meningitis in developing countries is uncertain, case fatality rates range from 10 to 30 per cent. The recent GBD 2010 study estimated that there were 422,900 deaths from meningitis in 2010, a decrease of 14.1 per cent from 1990 (Lozano et al. 2012). Even if effective treatment is provided, between 10 and 50 per cent of survivors still develop neurological sequelae. Successful outcome of neonatal meningitis relates to several factors including age, time, and clinical stability before effective antibiotic treatment, species of microorganism, number of bacteria or quantity of active bacterial products in the CSF at the time of diagnosis, intensity of the host's inflammatory response, and time elapsed to sterilize CSF cultures. The highest rates of mortality and morbidity occur following meningitis in the neonatal period.

Aetiology

The three most common bacterial pathogens, *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*, account for more than 80 per cent of cases of bacterial meningitis in the United States overall

Table 8.11.8 Aetiology and treatment of bacterial meningitis

Patient group	Common organisms	Antimicrobial therapy
Immunocompetent children (age ≥ 3 months–18 years)	<i>H. influenzae</i> <i>S. pneumoniae</i> <i>N. meningitidis</i>	Developing countries: ampicillin plus chloramphenicol Developed countries: vancomycin plus a third-generation cephalosporin (cefotaxime or ceftriaxone ^a)
Immunodeficient, pregnant, and elderly (> 50 years)	<i>L. monocytogenes</i> <i>S. pneumoniae</i> <i>N. meningitidis</i> Aerobic Gram-negative bacilli	Vancomycin plus ampicillin plus either cefipime or meropenem
Neurosurgical problems and head trauma	<i>S. aureus</i> <i>S. pneumoniae</i>	Vancomycin plus a third-generation cephalosporin or meropenem

^a For resistant *S. pneumoniae*, the American Academy of Pediatrics recommends vancomycin plus cefotaxime or ceftriaxone as empiric therapy.

Source: data from Brouwer, M.C. et al., Epidemiology, diagnosis, and antimicrobial treatment of acute bacterial meningitis, *Clinical Microbiology Reviews*, Volume 23, Number 3, pp. 467–492, Copyright © 2010, American Society for Microbiology. All Rights Reserved.

(Brouwer et al. 2010), although *Listeria monocytogenes* is a greater problem for the elderly, immunocompromised, and pregnant women (Table 8.11.8). There is a relative paucity of microbiological information from developing countries, but beyond the neonatal period, the main agents of meningitis include Hib, *S. pneumoniae*, and *Neisseria meningitidis* with reported case-fatality rates of 7.7, 10, and 3.5 per cent, respectively. Table 8.11.9 shows the common bacteria causing meningitis in developing and developed countries and recommended antibiotics for treatment (van de Beek et al. Lancet 2012).

Issues in presentation and diagnosis

The clinical features that may help in diagnosing meningitis are summarized in Table 8.11.10. In general, clinicians should have a low threshold for investigating and excluding meningitis in children, as features may be non-specific. The clinical diagnosis can be confirmed by lumbar puncture and the examination of CSF. The CSF will have a cloudy appearance, elevated protein, increased leucocyte counts with a predominance of neutrophils, and the presence of pathogens on Gram stain and/or culture provide a definitive diagnosis of bacterial meningitis. The use of latex agglutination or the *S. pneumoniae* C-polysaccharide antigen test (BinaxNOW®) may help confirm the diagnosis, especially if the child has been pre-treated with antibiotics (Saha et al. 2005). A bacterial meningitis score has been shown to have an excellent negative predictive value for the presence of bacterial meningitis. If patients do not have one of the following factors—positive CSF

Gram stain, CSF absolute neutrophil count ≥1000 cells/microlitre, CSF protein ≥80 mg/dL, peripheral blood absolute neutrophil count ≥10,000 cells/microlitre, or history of seizure before or at the time of presentation—they are very unlikely to have bacterial meningitis (negative predictive value = 99.9 per cent) (Nigrovic et al. 2007). In recent years, polymerase chain reaction (PCR) techniques for diagnosis of bacterial meningitis have become available with sensitivities ranging from 80 to 100 per cent and specificities of 95 to 100 per cent (Brouwer et al. 2012).

Medical treatment

The mainstay of treatment is prompt antibiotic therapy for suspected bacterial meningitis. Antibiotics need to be started before the results of CSF culture and sensitivity are available. This requires selection of an appropriate antibiotic, known to be effective against the common bacterial pathogens prevalent locally. An increasing number of beta-lactamase-producing strains of Hib are resistant to ampicillin, and a smaller number of chloramphenicol

Table 8.11.9 Comparison of bacterial meningitis aetiology in children in the developing and developed world (prior to the widespread introduction of the Hib vaccine)

	Developing countries	Developed countries
<i>H. influenzae</i>	30%	65%
<i>S. pneumoniae</i>	23%	13%
<i>N. meningitidis</i>	28%	18%
Other organisms	19%	4%

Table 8.11.10 Signs and symptoms of paediatric meningitis

Symptoms or presenting history	Signs

Focal paralysis in any limbs or trunk	
Irregular breathing	

acetyltransferase-producing strains are resistant to chloramphenicol. Additionally, the proportion of CSF isolates of *S. pneumoniae* that is non-susceptible to penicillin, ceftriaxone, and cefotaxime has also increased. Currently, the drugs for suspected or confirmed bacterial meningitis include vancomycin plus an extended spectrum cephalosporin with the addition of ampicillin if *L. monocytogenes* is suspected. If these options are not available, then ampicillin + either gentamicin or chloramphenicol may be used. If sepsis is suspected, then cases should be treated with ampicillin or penicillin plus an aminoglycoside, until meningitis is confirmed. Antimicrobial therapy is described further in Table 8.11.8.

Very early parenteral administration of corticosteroids (before or with initiation of antibiotics) significantly reduces severe adverse outcomes and case fatality rates. Similarly, there is evidence to suggest that restriction of fluids in the first 48 hours may improve outcomes. A meta-analysis of randomized, controlled trials has shown the benefit of steroids in all-cause bacterial meningitis, predominantly Hib meningitis. A recent Cochrane systematic review found that corticosteroids protect against severe hearing loss and neurological sequelae, and reduce mortality among adults with community-acquired bacterial meningitis in high-income countries (van de Beek et al. 2007). While this review found evidence of a benefit for children from resource-rich countries, there was no beneficial effect of corticosteroids for children in low-income countries.

Preventive measures

Although poverty, malnutrition, overcrowding are important risk factors for disease, delayed and inappropriate case management is a common determinant of adverse outcomes. The development of effective vaccines has been a major factor in the reduction of the burden of meningitis in the developed world. These include the Hib, pneumococcal conjugate, and meningococcal vaccines.

Haemophilus influenzae type b vaccine

Currently three Hib conjugate vaccines are available for use in infants and young children with comparable efficacy (protective efficacy of Hib against development of laboratory confirmed invasive disease > 90 per cent). All industrialized countries now include Hib vaccine in their national immunization programmes, resulting in the virtual elimination of invasive Hib disease. There is comparable impressive evidence of benefit from several developing countries following introduction of Hib vaccine and many countries now include Hib vaccine in their repertoire with GAVI support.

Pneumococcal vaccine

The older 23-valent pneumococcal polysaccharide vaccine is unsuitable for use in young children. The recent development of the 7-valent protein-conjugate polysaccharide vaccine, 10-valent, and 13-valent vaccines is a major advance in the control of invasive pneumococcal disease. In the United States, the 7-PCV was included in routine vaccinations of infants and children under 2 years in 2000 and by 2001 the incidence of all invasive pneumococcal disease in this age group had declined by 69 per cent. Currently several Latin American countries are beginning to introduce pneumococcal conjugate vaccine as part of the WHO

Expanded Program on Immunization (EPI) as are several countries in sub-Saharan Africa and Asia.

Meningococcal vaccine

Meningococcal polysaccharide vaccine is available for serogroups A, C, W-135, and Y. This quadrivalent vaccine is being introduced in several developed countries as part of routine vaccine schedules, especially for adolescents who will be rooming in crowded dormitories while attending university. In many developed countries this vaccine has been replaced by the quadrivalent meningococcal conjugate vaccine, which is more immunogenic and, because it induces memory cells, is likely to lead to a longer lasting protective immune response. Recent evidence of the efficacy and safety of a conjugate meningococcal B vaccine suggests that in the near future we will have highly effective vaccines for all major meningococcal serogroups (Vesikari et al. 2013).

Gastrointestinal tract infections

Diarrhoea, the most common manifestation of intestinal tract infections, is a leading cause of preventable death in most developing countries where its greatest impact is seen in infants and children. Infectious diarrhoea may be accompanied by numerous complications (Table 8.11.11). The financial burden associated with medical care and lost productivity due to infectious diarrhoea amounts to more than US\$20 billion a year in the United States alone.

Invasive diarrhoea refers to diarrhoea caused by bacterial pathogens that invade the bowel mucosa, causing inflammation and tissue damage and may cause blood in stools (bloody diarrhoea). Invasive diarrhoea accounts for approximately 10 per cent of diarrhoeal episodes in children under 5 years of age and approximately 15 per cent of diarrhoea-associated deaths in this age group worldwide. Although less frequent, bloody diarrhoea generally lasts longer, is associated with higher risk of complications and case fatality rates, and is more likely to adversely affect a child's growth. The burden of disease is mainly in younger age groups; 72 per cent of deaths from diarrhoea and 81 per cent of deaths from pneumonia happen in children younger than 2 years. Pneumonia incidence falls less rapidly with age than does mortality from the disease. Diarrhoea incidence peaks at age 6–11 months and then decreases with age; proportionate mortality is highest from age 0–11 months, the ages at which the risk of disease and severe disease also peak (Fig. 8.11.2) (Fischer Walker et al. 2013).

Global and regional epidemiology

The aetiology and severity of gastrointestinal infections are determined by several epidemiological factors. Young children and the elderly are at greatest risk for more severe disease and complications. The presence of underlying medical conditions, especially those that compromise immunity, greatly enhances the risk of acquiring an infection and its ultimate severity. Poor sanitation, inadequate water supplies, and increasing globalization of food transport systems all predispose to the development of large epidemics of food- and water-borne outbreaks of gastrointestinal disease. Seasonal or cyclic weather variations also influence the epidemiology of diarrhoeal disease and food poisoning.

Several recent reviews have evaluated diarrhoea burden and mortality rates. A review carried out two decades ago estimated

Table 8.11.11 Complications of gastrointestinal infections

Complication	Causative pathogens
Dehydration	<i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i> (especially in immunocompromised hosts), enterotoxigenic <i>Escherichia coli</i> (ETEC), rotavirus
Severe vomiting	Staphylococcal food poisoning, norovirus, rotavirus
Haemorrhagic colitis	<i>Campylobacter jejuni</i> , enterohaemorrhagic <i>E. coli</i> (EHEC), <i>Salmonella</i> , <i>Shigella</i> , <i>V. parahaemolyticus</i>
Toxic megacolon, intestinal perforation	EHEC, <i>Shigella</i> , <i>C. jejuni</i> (rare), <i>Clostridium difficile</i> (rare), <i>Salmonella</i> (rare), <i>Yersinia</i> (rare)
Haemolytic uraemic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)	EHEC, <i>Shigella</i> , <i>C. jejuni</i> (rare)
Reactive arthritis	<i>C. jejuni</i> , <i>Shigella</i> , <i>Salmonella</i> , <i>Yersinia</i>
Malabsorption/malnutrition	<i>Cyclospora cayetanensis</i> , <i>Giardia lamblia</i> , <i>C. parvum</i> or <i>C. hominis</i> (especially immunocompromised hosts)
Distant metastatic infection	<i>Salmonella</i> , <i>C. jejuni</i> (rare), <i>Yersinia</i> (rare)
Guillain–Barré syndrome	<i>C. jejuni</i> (rare)

that 4.6 million children died annually from diarrhoea. Kosek et al. have updated these estimates by reviewing 60 studies of diarrhoea morbidity and mortality published between 1990 and 2000 (Kosek et al. 2003). They concluded that diarrhoea accounts for 21 per cent of all deaths at less than 5 years of age and causes 2.5 million deaths per year, although morbidity rates remain relatively unchanged. Despite the different methods and sources of information, each successive review of the diarrhoea burden over the past three decades has demonstrated declining mortality but relatively stable morbidity rates. Persistent high rates of diarrhoea morbidity may have significant long-term effects on linear growth and physical and cognitive function in children. Fig. 8.11.3 shows country-specific global trends for diarrhoea and pneumonia in the world from 2000 to 2010.

**Fig. 8.11.2** Distribution of cases of, and deaths from, diarrhoea and pneumonia in children aged 0–4 years.

Aetiology

Common aetiologies of non-inflammatory diarrhoea include enterotoxigenic *E. coli* (ETEC) and other strains such as enteroaggregative (EAEC), diffusely adhering, and enteropathogenic *E. coli*, *Vibrio cholerae*; non-O1 cholerae such as *V. vulnificus*; parasites including *Giardia lamblia*, *Cryptosporidium parvum*, and microsporidia; and several different virus species including rotavirus, noroviruses, and astroviruses (Hamer and Gorbach 2010). Acute inflammatory diarrhoea is the result of infection with bacterial enteropathogens such as *Shigella*, *Campylobacter*, *Salmonella* spp., enterohaemorrhagic *E. coli* (EHEC), *V. parahaemolyticus*,

**Fig. 8.11.3** Annual rates of change in diarrhoea-specific and pneumonia-specific mortality between 2000 and 2010. The 75 Countdown to 2015 countries are shown; the 15 countries with the highest burdens are labelled. Dotted lines show target annual rates of change to achieve the MDG-4. DRC, Democratic Republic of the Congo.

and *Clostridium difficile*. Among the parasites, *Entamoeba histolytica* is the most common cause of dysenteric illness although *Balantidium coli*, *Schistosoma mansoni*, *S. japonicum*, *Trichuris trichiura*, hookworms, and *Trichinella spiralis* can all cause bloody, mucoid diarrhoea.

Estimates of rotavirus and cholera as major diarrhoea aetiologies associated with increased risk of mortality are shown in Table 8.11.12 (Fischer Walker et al. 2013).

Notwithstanding these estimates from a systematic review of available literature, more robust data on diarrhoea aetiology are now available. The recent large multicountry study of diarrhoea aetiology, the Global Enterics Multi-Center Study (GEMS) (Kotloff et al. 2013), has provided much-needed insight into the aetiology of severe diarrhoea in young children. Fig. 8.11.4 provides the attributable incidence of moderate to severe diarrhoea among young children in low-income settings, stratified by age.

Infectious microorganisms in contaminated food and drink are the main source of travellers' diarrhoea. High-risk foods include uncooked vegetables, salsa, meat, and seafood. Tap water, ice, unpasteurized milk and dairy products, salads, and unpeeled fruits are also associated with an increased risk. Although many different pathogens may be responsible, the leading culprits are various forms of *E. coli*, particularly ETEC and EAEC. *C. jejuni* is encountered in a significant proportion of cases, particularly

during cooler seasons. Viruses, *Shigella*, *Salmonella*, *Giardia*, *Cryptosporidium*, and *Cyclospora* spp. are responsible for a minority of travellers' diarrhoea cases.

Food poisoning is most commonly caused by the consumption of food contaminated with bacteria or bacterial toxins. Food poisoning can also be due to parasites (e.g. trichinosis), viruses (e.g. hepatitis A), and other toxins (e.g. *Amanita* mushrooms). The most well-recognized causes of bacterial food poisoning are the following: *Clostridium perfringens*, *S. aureus*, *Vibrio* spp. (including *V. cholerae* and *V. parahaemolyticus*), *Bacillus cereus*, *Salmonella* spp., *C. botulinum*, *Shigella* spp., toxigenic *E. coli* (ETEC and EHEC), and certain species of *Campylobacter*, *Yersinia*, *Listeria*, and *Aeromonas*.

Several risk factors have been demonstrated for diarrhoea-associated mortality including not breastfeeding, being underweight, stunting, wasting, vitamin A deficiency, and zinc deficiency (Fischer Walker et al. 2013).

Issues in presentation and diagnosis

Gastrointestinal infections usually result in three principal syndromes: non-inflammatory diarrhoea, inflammatory diarrhoea, and systemic disease. Non-inflammatory diarrhoea primarily involves the small intestine, whereas inflammatory diarrhoea predominantly affects the colon. The location of infection influences the clinical characteristics and certain diagnostic features of the

Table 8.11.12 Diarrhoea episodes and deaths by WHO region

Several diarrhoea episodes	African region	American region	Eastern Mediterranean region	European region	Southeast Asian region	Western Pacific region	World

diarrhoeal disease (Table 8.11.13). Thus, organisms that target the small intestine tend to produce watery, potentially dehydrating diarrhoea, while those infecting the large intestine cause bloody mucoid diarrhoea associated with tenesmus.

Acute watery diarrhoea can be rapidly dehydrating, with stool losses of 250 mL/kg/day or more, a quantity that quickly exceeds

total plasma and interstitial fluid volumes, and is incompatible with life unless aggressive fluid therapy can be provided. Such dramatic dehydration is usually due to rotavirus, ETEC, or *V. cholerae*, and it is most dangerous in the very young.

Persistent diarrhoea is defined as diarrhoea lasting 14 days or longer, is manifested by malabsorption, nutrient losses, and

Table 8.11.13 Clinical features and aetiologies of diarrhoeal diseases

Feature	Site of infection	
	Small intestine	Large intestine
Pathogens	<i>Escherichia coli</i> (enteropathogenic <i>E. coli</i> , enterotoxigenic <i>E. coli</i>) <i>Cryptosporidium parvum</i> <i>Giardia lamblia</i> Norovirus Rotavirus <i>Vibrio cholerae</i>	<i>E. coli</i> (EIEC, EHEC) <i>Entamoeba histolytica</i> <i>Shigella</i> spp.
Location of pain	Mid abdomen	Lower abdomen, rectum
Volume of stool	Large	Small
Blood in stool	Rare	Common
Faecal leucocytes	Rare	Common (except in amoebiasis)
Sigmoidoscopy	Normal	Mucosal ulcers, haemorrhagic foci, friable mucosa

wasting, and is typically associated with malnutrition. Although persistent diarrhoea accounts for 8–20 per cent of diarrhoea episodes, it is associated with a disproportionately increased risk of death. Persistent diarrhoea more commonly follows an episode of bloody diarrhoea and is associated with a tenfold higher risk of mortality. HIV infection is another risk factor for persistent diarrhoea in both adults and children.

Inflammatory diarrhoea is a manifestation of invasive intestinal infection that is associated with intestinal damage and nutritional deterioration, often with systemic manifestations including fever. Although clinicians often use the term bloody diarrhoea interchangeably with dysentery, the latter is a syndrome consisting of the frequent passage of characteristic, small-volume, bloody mucoid stools, abdominal cramps, and tenesmus. Agents that cause bloody diarrhoea or dysentery can also provoke a form of diarrhoea that does not present clinically with visible blood in the stool, although mucosal damage and inflammation are present and faecal blood and white blood cells are usually detectable by microscopy.

Because of the significant morbidity and costs associated with infectious diarrhoea, making a specific laboratory diagnosis can be useful epidemiologically, diagnostically, and therapeutically. A definitive diagnosis is achieved mainly through study of faecal specimens, using bacteriological culture, viral culture, or direct electron microscopy for viral particles, and identification of microbial antigens (viruses, bacteria, parasites, or toxins). DNA probes, PCR, and immunodiagnostic tests can now be used to identify several pathogens in stool specimens. Although some diseases can be diagnosed by elevations of serum antibody titres, this method is usually retrospective and often inaccurate.

Evidence-based interventions

Increased use of oral rehydration therapy, improved nutrition, increased breastfeeding, better supplemental feeding, female education, measles immunization, and improvement in hygiene

and sanitation are believed to have contributed to the decline in morbidity and mortality of diarrhoea. Syndromic diagnosis provides important clues to optimal management and is both programmatically and epidemiologically relevant. The correct treatment of diarrhoea requires mothers to recognize the problem and seek medical care promptly, and health workers to give oral rehydration solution (ORS) or other fluids to prevent or treat dehydration, dispense an appropriate antibiotic when needed, provide advice on appropriate feeding, and provide follow-up, especially for children at increased risk of serious morbidity or death. In recent years, low-osmolarity ORS and zinc supplementation (10–20 mg/day) have led to significantly improved diarrhoea outcomes (Aggarwal 2007). A recent series in *The Lancet* (Bhutta et al. 2013b) highlighted the role of 15 core interventions to address childhood pneumonia and diarrhoea, of which several are also common nutrition interventions underscored recently (Table 8.11.14) (Bhutta et al. 2013a).

Medical treatment

Since the most devastating consequences of acute infectious diarrhoea result from fluid losses, the major goal of treatment is the replacement of fluid and electrolytes. While the intravenous route of administration has been traditionally used, ORS has been shown to be equally effective physiologically and logistically more practical and less costly to administer, especially in developing countries. ORS is the treatment of choice for mild-to-moderate diarrhoea in both children and adults, as long as vomiting is not a major feature of the gastrointestinal infection. ORS can also be used in severely dehydrated patients after initial parenteral rehydration.

Although there is no doubt about the value of ORS in treating dehydrating diarrhoea, the optimal sodium concentration of the solution remains in dispute, particularly in regard to the treatment of mild-to-moderate diarrhoea in well-nourished children in industrialized countries. The high concentration of sodium

Table 8.11.14 Interventions for prevention and treatment of diarrhoea, pneumonia, and undernutrition

Diarrhoea	Pneumonia	Nutrition
Breastfeeding promotion	Breastfeeding promotion	Breastfeeding promotion
Improved water source, sanitation and hygiene	Improved water source, sanitation and hygiene	Improved water source, sanitation and hygiene
Preventive vitamin A supplementation	Preventive vitamin A supplementation	Preventive vitamin A supplementation
Preventive zinc supplementation	Preventive zinc supplementation	Preventive zinc supplementation
Rotavirus vaccine	Hib vaccine	Periconceptional folic acid supplementation or fortification
ORS	Pneumococcal vaccine	Appropriate complementary feeding
Zinc—for treatment of diarrhoea	Case management of neonatal infections	Maternal balanced energy protein supplementation
Antibiotics for dysentery	Oral antibiotics: case management of pneumonia in children	Maternal calcium supplementation
		Multiple micronutrient supplementation in pregnancy
		Management of moderate and severe acute malnutrition

Source: data from *The Lancet*, Volume 382, Issue 9890, Bhutta, Z.A. et al., Evidence based interventions for improvement of maternal and child nutrition: what can be done and at what cost?, pp. 452–477, Copyright © 2013 Elsevier Ltd All rights reserved.

(90 mmol) in the standard WHO ORS formulation may cause hypernatraemia and even seizures in children with non-cholera watery diarrhoea. Consequently, lower concentrations of sodium and a reduced osmolality solution have been found to be effective for rehydration and not to be associated with any serious adverse clinical events (Hanh et al. 2001). The substitution of starch derived from rice or cereals for glucose in ORS has been another approach. Rice-based salt solutions produce lower stool losses, a shorter duration of diarrhoea, and greater fluid and electrolyte absorption than do glucose-based solutions in treating childhood and adult diarrhoea. ORS has major advantages over home fluids in the management of children with significant dehydration and coupled with zinc therapy (20 mg zinc sulphate daily for 10 days) is the mainstay of treatment of childhood diarrhoea.

Dietary abstinence, the traditional approach to an acute diarrhoeal illness, restricts the intake of necessary calories, fluids, and electrolytes. During an acute attack, the patient often finds it more comfortable to avoid spicy, high-fat, and high-fibre foods, all of which can increase stool volume and intestinal motility. Although giving the bowels a rest provides symptomatic relief, continued oral intake of fluids and foods is critical for both rehydration and the prevention of malnutrition. In children, it is particularly important to restart feeding as soon as the child is willing to accept oral intake.

Because certain foods and fluids can increase intestinal motility, it is wise to avoid fluids such as coffee, tea, cocoa, and alcoholic beverages. Ingestion of milk and dairy products can potentiate fluid secretion and increase stool volume. Besides the oral rehydration therapy outlined earlier, acceptable beverages for mildly dehydrated adults include fruit juices and various bottled soft drinks. Carbonated drinks should be allowed to 'de-fizz' by letting them stand in a glass before ingestion. Soft, easily digestible foods are generally acceptable to the patient with acute diarrhoea.

Since most patients with infectious diarrhoea, even those with a recognized pathogen, have a mild, self-limited course, neither a stool culture nor specific treatment is required for such cases. For more severe cases, however, empirical antimicrobial therapy should be instituted, pending the results of stool and blood cultures. Gastrointestinal infections likely to respond to antibiotic treatment include cholera, giardiasis, cyclosporiasis, shigellosis, *E. coli* diarrhoea in infants, symptomatic travellers' diarrhoea, and *C. difficile* diarrhoea. The choice of antimicrobial drug should be based on *in vitro* sensitivity patterns, which vary from region to region. A fluoroquinolone antibiotic is a good choice for empirical therapy, since these agents have broad-spectrum activity against virtually all bacterial pathogens responsible for acute infectious diarrhoea (except *C. difficile*). Resistance to fluoroquinolones in South and South East Asia is an increasing problem.

In patients with severe community-acquired diarrhoea—characterized by more than four stools per day lasting for at least 3 days or more with at least one associated symptom such as fever, abdominal pain, or vomiting—there is a high likelihood of isolating a bacterial pathogen. In this setting, a short course of a fluoroquinolone, namely 1–3 days' duration, will generally provide prompt relief with a low risk of adverse effects. Fluoroquinolones will not be effective for parasitic infections—specific antiparasitic drugs should be prescribed after identification of the offending pathogen in stool smears.

The duration of antimicrobial therapy has not been clearly defined. While courses of anywhere from 3 to 10 days of treatment have been recommended, there are several studies that included severe forms of diarrhoea which suggested that a single dose is as effective as more prolonged therapy. For example, single-dose fluoroquinolone therapy is highly effective for infections due to *V. cholerae*, *V. parahaemolyticus*, and most *Shigella* species. On the other hand, short-course treatment of salmonella gastroenteritis with fleroxacin has not been found to be clinically beneficial. When treatment is indicated, a number of studies have shown that the combination of an antimicrobial drug and an antimotility drug provides the most rapid relief of diarrhoea.

Preventive measures

Diarrhoeal disease affects rich and poor, old and young, and those in developed and developing countries alike, yet a strong relationship exists between poverty, an unhygienic environment, and the number and severity of diarrhoeal episodes—especially for children under 5 years. Poverty also restricts the ability to provide age-appropriate, nutritionally balanced diets, or to modify diets when diarrhoea develops so as to mitigate and repair nutrient losses. The impact is exacerbated by the lack of adequate, available, and affordable medical care. Thus preventive and management strategies for diarrhoea must have an equity focus.

Malnutrition is an independent predictor of the frequency and severity of diarrhoeal illness and can lead to a vicious cycle in which sequential diarrhoeal disease leads to increasing nutritional deterioration, impaired immune function, and greater susceptibility to infection.

Family knowledge about diarrhoea must be reinforced in areas such as prevention, nutrition, hand washing and hygiene, measles vaccination, preventive zinc supplements, and when and where to seek care. It is estimated that, in the 1990s, more than 1 million deaths related to diarrhoea may have been prevented each year, largely attributable to the promotion and use of these therapies.

A meta-analysis of three observational studies in developing countries shows that breastfed children under the age of 6 months are 6.1 times less likely to die of diarrhoea than infants who are not breastfed. Continued breastfeeding during the diarrhoea episode provides nutrients to the child, prevents weight loss, and improves recovery from diarrhoea. Contaminated and poor-quality complementary foods are associated with increased diarrhoea burden and stunting (Huttly et al. 1997). Ideally, complementary foods should be introduced at 6 months of age, and breastfeeding should continue for up to 2 years or even longer. Appropriate, safe, and aptly initiated complementary feeding has been shown to significantly reduce mortality in young children. Diarrhoea frequently causes fever, altering host metabolism and leading to the depletion of body stores of nutrients. These losses must be replenished during convalescence, which takes much longer than the illness does to develop. For these reasons, appropriate feeding strategies during diarrhoea episodes are a cornerstone of treatment.

Probiotics, especially *Lactobacillus rhamnosus* GG, effectively reduce the frequency and duration of diarrhoea in children and adults. Probiotics are also useful for the prevention of antibiotic-associated diarrhoea.

Various studies suggest that zinc-deficient populations are at increased risk of developing diarrhoeal diseases, respiratory tract infections, and growth retardation. A meta-analysis published in

1999 showed that continuous zinc supplementation was associated with decreased rates of childhood diarrhoea (Zinc Investigator's Collaborative Group 1999), and a meta-analysis confirms the previous findings and indicates that zinc supplementation for young children leads to reduction in diarrhoea risk (by 14 per cent), serious forms of diarrhoea, and the number of days of diarrhoea per child (Aggarwal et al. 2007).

Human faeces and contamination are the primary source of diarrhoeal pathogens. Poor sanitation, lack of access to clean water, and inadequate personal hygiene are responsible for an estimated 90 per cent of childhood diarrhoea. Promotion of hand washing reduces diarrhoea incidence by an average of 33 per cent and rigorous observational studies demonstrated a median reduction of 55 per cent in all-cause child mortality associated with improved access to sanitation facilities. Hand washing promotion strategies have also been shown to reduce diarrhoea burden with ancillary benefits in community settings.

Strict adherence to food and water precautions as already outlined will help those who travel to less developed areas of the world to decrease their risk of acquiring gastrointestinal infections. Parasitic infections, such as strongyloidiasis and hookworms, can be avoided by the use of footwear. Avoiding contact with fresh-water such as rivers and lakes in endemic areas serves to prevent schistosomiasis.

Immunization represents an ideal way to prevent certain bacterial and viral diseases, but has not yet proved successful for combating many gastrointestinal pathogens. The cholera vaccine that has been available for decades suffers from low efficacy, a moderate risk of side effects, and a short duration of action. Newer oral cholera vaccines, such as the inactivated B subunit vaccine, are highly effective for prevention of severe cholera. New rotavirus vaccines have not been associated with intussusception. Measles is known to predispose to diarrhoeal disease secondary to measles-induced immunodeficiency, and it is estimated that measles vaccine at varying levels of coverage (45–90 per cent) could prevent 44–64 per cent of measles cases, 0.6–3.8 per cent of diarrhoeal episodes, and 6–26 per cent of diarrhoeal deaths among children under 5 years. Global measles immunization coverage is now approaching 80 per cent, and the disease has been eliminated from the Americas, raising hopes for global elimination in the near future, with a predictable reduction in diarrhoea as well.

Typhoid fever

Typhoid fever, a systemic disease caused by *Salmonella enterica* serovar Typhi, is an acute illness characterized by protean and non-specific symptoms, including fever and gastrointestinal infection. The systemic disease caused by *S. Paratyphi* (A, B, or C) is also clinically similar; both typhoid and paratyphoid are collectively labelled as enteric fevers. The emergence of drug-resistant strains, especially multidrug-resistant (MDR) *S. Typhi*, resistant to ampicillin, chloramphenicol, trimethoprim–sulphamethoxazole, and, more recently, fluoroquinolones, is a growing problem.

Global and regional epidemiology

The global incidence of typhoid fever in 2000 was estimated to be 21.6 million cases, with more than 200,000 deaths (Crump et al. 2004). Approximately 12.5 million cases of typhoid fever occur annually in the developing world (excluding China),

Table 8.11.15 Crude typhoid incidence rates by region, 2000

Area/region	Crude incidence ^a	Typhoid cases	Incidence classification
Global	178	10,825,487	High
Africa	50	408,837	Medium
Asia	274	10,118,879	High
Europe	3	19,144	Low
Latin America/Caribbean	53	273,518	Medium
Northern America	< 1	453	Low
Oceania	15	4656	Medium

^a Per 100,000 persons per year.

with 7.7 million cases in Asia alone. In South Asia, recent community-based studies indicate that a large proportion of cases occur in children under 5, with significant morbidity and mortality. The global case fatality rate of 1 per cent is based on conservative estimates from hospital-based fever studies; actual mortality figures may be higher in areas where referral is difficult and health services are dysfunctional. Table 8.11.15 shows the regional distribution of crude typhoid incidence rates.

There have been dramatic point-source outbreaks of typhoid related to contamination of food sources or water supply. The use of contaminated ground water, consumption of street foods, and poor personal hygiene are common risk factors for infection.

Issues in presentation and diagnosis

After ingestion in contaminated food or water, *S. Typhi* penetrates the small bowel mucosa and makes its way rapidly to the lymphatics, the mesenteric nodes, and finally the bloodstream. Following an initial bacteraemia, the organism is sequestered in cells of the reticuloendothelial system where it multiplies and re-emerges several days later in recurrent waves of bacteraemia, an event that initiates the symptomatic phase of infection. The incubation period ranges from 5 to 14 days.

Typhoid fever is a febrile illness of prolonged duration, characterized by hectic fever, delirium, persistent bacteraemia, splenomegaly, and a variety of systemic manifestations. Most children present with fever, headache, and abdominal discomfort, diarrhoea, sore throat, anorexia, dry cough, or myalgia and constipation. In the later phase of illness, more specific physical signs including hepatomegaly and splenomegaly may be observed. Rose spots may be seen in an early stage of the illness in fair-skinned children and large proportions have a centrally coated tongue (Bhan et al. 2005). Pulse–temperature dissociation is present in some patients. In approximately 50 per cent of patients, there is no change in bowel habits; in fact, constipation is more common than diarrhoea in children with typhoid fever. As a result of recurrent waves of bacteraemia, patients with typhoid fever can develop pneumonia, pyelonephritis, osteomyelitis, septic arthritis, and

meningitis. Intestinal haemorrhage and perforation, the most common complications, often occur in the 3rd week of infection or during convalescence. The most serious complication, intestinal perforation, occurs in 0.5–3 per cent of the patients with typhoid, and because they occur most commonly in areas where optimal medical care is not readily available, it may be associated with case fatality rates ranging from 4.8 to 30.5 per cent. Recent elucidation of a *S. Typhi* specific toxin (Song et al. 2013) not only provides exciting new information on the pathogenesis of typhoid fever but also opens exciting possibilities of development of newer vaccines and interventions for this disease.

Diagnosis of typhoid and paratyphoid fever requires culture of blood, bone marrow, stools, or urine to confirm growth of *S. Typhi*. Laboratory findings commonly include leucopenia, thrombocytopenia, proteinuria, and elevated transaminases, but these are relatively non-specific and uncommon. In developing countries, culture facilities are expensive and mostly confined to hospitals, while most typhoid patients are diagnosed clinically and treated in outpatient settings. In other instances, serological diagnosis may be made with the Widal test. The latter, though useful, is insufficiently sensitive in endemic areas. Newer diagnostic tests have been developed, such as the Typhidot and Tubex, which detect IgM antibodies against specific *S. Typhi* antigens (Bhutta 2006). Since these newer assays have not proven to have adequate sensitivity and specificity for routine use in community settings, there is a need for further refinement in serological or molecular diagnosis of the disease.

Medical treatment

In the pre-antibiotic era, typhoid fever case fatality rates approached 20 per cent. Treatment with effective antimicrobial agents—ampicillin, chloramphenicol, co-trimoxazole, and later ciprofloxacin—has progressively reduced case fatality rates to less than 1 per cent, except for MDR isolates. Fluoroquinolones and third-generation cephalosporins are effective in MDR typhoid but over the last few years there have been increasing reports in Asia of *S. Typhi* strains with reduced fluoroquinolone susceptibility. The presence of nalidixic acid resistance *in vitro* is associated with clinical treatment failures with fluoroquinolones. Alternative therapies including azithromycin or third-generation cephalosporins are recommended in these circumstances. Given the considerable morbidity and higher mortality rates reported with MDR typhoid in children, appropriate antibiotic therapy must be instituted promptly and, when appropriate facilities are available, treatment choices should be guided by susceptibility testing.

Preventive measures

Detection of sources of infection related to recent typhoid fever in household contacts, commercial food handlers, or contaminated drinking water sources is essential to design effective preventive measures for disease containment.

Although the old whole-cell-inactivated typhoid vaccine has been withdrawn because of side effects, there are two licensed vaccines for prevention of disease: Ty21a (an attenuated strain of *S. Typhi* administered orally) and Vi (the purified bacterial polysaccharide vaccine, given parenterally). These two vaccines have comparable protective efficacy and while they have been largely

used for travellers, recently the Vi vaccine has been used for school vaccination programmes in large public health settings in Asia. For younger children and infants the Vi conjugate vaccine has been shown to provide a high degree of protection in a series of studies in Vietnam. However, the conjugate vaccine has as yet not been produced for public health use.

Dengue fever

In recent years, dengue fever, a mosquito-borne arboviral disease, has become one of the most common and rapidly spreading vector-borne diseases (after malaria) and thus now represents a major international public health concern. Dengue virus belongs to the genus *Flavivirus* (single-stranded, non-segmented RNA viruses), which includes four serologically distinct serotypes (DEN-1, DEN-2, DEN-3, and DEN-4). Variations in virus strains within and between the four serotypes influence disease severity. There is limited protection across serotypes. Secondary infections (particularly with serotype 2) are more likely to result in severe disease and dengue haemorrhagic fever.

Global and regional epidemiology

Humans and mosquitoes are the principal hosts of dengue virus although some non-human primates can also be infected. Dengue epidemics occur during the warm, humid, rainy seasons, which favour breeding conditions for the mosquito vector, *Aedes aegypti*. More than two-fifths of the world's population (~2.5 billion) lives in areas potentially at risk for dengue, which is endemic in more than 100 countries across the globe, with tropical areas of Asia, the Western Pacific, Latin America, and the Caribbean being the most seriously affected regions.

In some case series, dengue fever has been reported as the second most frequent cause of hospitalization (after malaria) among travellers returning from the tropics. It causes an estimated 50–100 million illnesses annually, including 250,000–500,000 cases of dengue haemorrhagic fever—a severe manifestation of dengue—and 14,700–24,000 deaths (Deen et al. 2006; Lozano et al. 2012). Around 95 per cent of cases occur in children less than 15 years of age, with infants representing 5 per cent of the cases.

Issues in presentation and diagnosis

The incubation period can vary from 3 to 14 days (typically between 5 and 7 days) and viraemia can persist up to 12 days (typically 4–5 days). Fever usually lasts for 5–7 days; fevers persisting beyond 10–14 days suggest another diagnosis. The clinical features of dengue vary with patient age. Most dengue infections, especially in children, are minimally symptomatic or asymptomatic. Children may also present with atypical syndromes such as encephalopathy and fulminant liver failure.

Classic dengue fever is characterized by a high fever of abrupt onset, sometimes with two peaks (saddle back fevers), severe myalgias, arthralgia, retro-orbital pain, headaches, and any of the three types of rashes, including a petechial rash, diffuse erythematous rash with isolated patches of normal skin, and a morbilliform rash, haemorrhagic manifestations, and leucopenia. Other manifestations include flushed facies, sore throat, cough, cutaneous hyperaesthesia, and taste aberrations. Convalescence

may be prolonged and complicated by profound fatigue and depression.

When the only haemorrhagic manifestation is provoked (by a tourniquet test), the case used to be categorized as grade I dengue haemorrhagic fever, but a spontaneous haemorrhage, even if mild, indicated grade II illness. Due to concerns about the widespread applicability of this grading system, it was updated by the WHO in recent years (WHO and Special Programme for Research and Training in Tropical Diseases 2009). Grades III and IV dengue haemorrhagic fever (incipient and frank circulatory failure, respectively) represent dengue shock syndrome which is characterized by sustained abdominal pain, persistent vomiting, sudden change from fever to hypothermia, alteration of consciousness, and a sudden drop in platelet count. Around 40 per cent of patients also have enlargement and tenderness of the liver. Rare presentations of infection include severe haemorrhage, severe hepatitis, rhabdomyolysis, jaundice, parotitis, cardiomyopathy, and variable neurological syndromes.

Infection with one serotype is thought to produce lifelong immunity to that serotype but only partial immunity to the others. Previous infection with a specific serotype followed by infection with a new serotype greatly increases the risk of dengue haemorrhagic fever.

Dengue virus serotypes are distinguishable by complement fixation and neutralization test. Other diagnostic tests for patients with dengue include packed cell volume, platelet count, liver function tests, prothrombin time, partial thromboplastin time, electrolytes, and blood gas analysis. Laboratory findings commonly associated with dengue include leucopenia, lymphocytosis, increased concentration of liver enzymes, and thrombocytopenia. Diagnosis can be confirmed with several laboratory tests, especially the haemagglutination inhibition test and IgG or IgM enzyme immunoassays. Platelet counts and haematocrit

determinations should be repeated at least every 24 hours to allow prompt recognition of the development of dengue haemorrhagic fever and institution of fluid replacement. Diagnostic criteria for dengue fever are provided in Fig. 8.11.5.

Evidence-based interventions

Rapid urbanization has led to an increase in the environmental factors that contribute to the proliferation of *Aedes* mosquitoes. These include uncontrolled urban development, inadequate management of water and waste, presence of a range of large water stores, and disposable, non-biodegradable containers that become habitats for the larvae. These factors can change a region from non-endemic (no virus present) to hypoendemic (one serotype present) to hyperendemic (multiple serotypes present).

Medical treatment

No specific therapeutic agents exist for dengue fever apart from analgesics and medications to reduce fever. Treatment is supportive; steroids, antivirals, or carbazochrome (which decreases capillary permeability) have no proven role. In contrast, ribavirin, interferon alpha, and 6-azauridine have shown some antiviral activity *in vitro*. Mild or classic dengue is treated with antipyretic agents such as acetaminophen, bed rest, and fluid replacement (usually administered orally and only rarely parenterally); most cases can be managed on an outpatient basis.

The management of dengue haemorrhagic fever and the dengue shock syndrome is purely supportive. Aspirin and other non-steroidal anti-inflammatory drugs should be avoided owing to the increased risk for Reye's syndrome and haemorrhage.

Preventive measures

In the absence of a vaccine, vector control is the only effective preventive measure. At a personal level, the risk of mosquito bites may be reduced by the use of protective clothing and repellents.

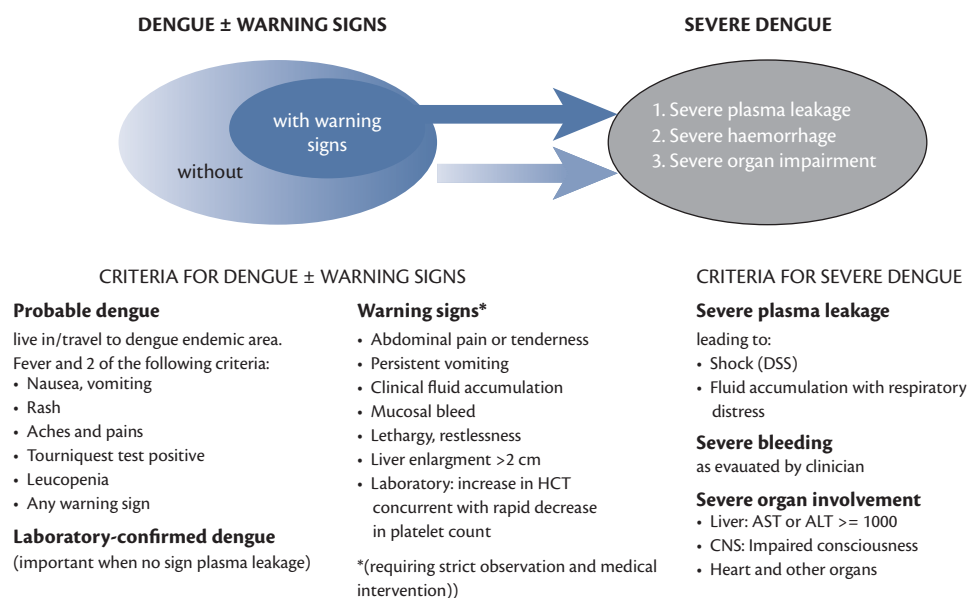

Fig. 8.11.5 Suggested dengue case classification and levels of severity.

Reproduced with permission from World Health Organization and Special Programme for Research and Training in Tropical Diseases, *Dengue Guidelines for Diagnosis, Treatment, and Prevention*, Copyright © World Health Organization 2009, available from: http://whqlibdoc.who.int/publications/2009/9789241547871_eng.pdf.

The single most effective preventive measure for travellers in areas where dengue is endemic is to avoid mosquito bites by using insect repellents containing *N*, *N*-diethyl-3-methyl-benzamide (DEET) or picaridin. The insect repellents should be used in the early morning and late afternoon, when *Aedes* mosquitoes are most active.

At a public health level, the risk of dengue fever outbreaks can be reduced by removing neighbourhood sources of stagnant water, especially within homes, using larvicides (especially for containers that cannot be eliminated), use of aerosolized insecticides, and introduction of predatory crustaceans.

Live attenuated tetravalent vaccines have been evaluated in phase 2 trials. Preliminary results demonstrated 80–90 per cent seroconversion rates in humans. A recently completed phase 2b trial of the recombinant, CYD tetravalent dengue vaccine in Thailand demonstrated an overall protective efficacy of 30 per cent with substantial variation among serotypes (Sabchareon et al. 2012). While the vaccine proved to be safe, protective efficacy ranged from 9 per cent for serotype 2 to 100 per cent for serotype 4. New approaches to vaccine development being studied include infectious clone DNA and naked DNA vaccines. These vaccines offer promise in terms of immunoprotection against all serotypes as well.

Parasitic infections

A broad range of parasites plagues humans worldwide. While certain parasites, such as the *Plasmodium* species that cause malaria, are well recognized and have received intensive international support for research and programmatic control interventions, others are considered among the world's most neglected diseases. Some of the main neglected tropical parasitic diseases include the protozoan infections such as human African trypanosomiasis, visceral leishmaniasis, and American trypanosomiasis (Chagas disease) and helminthic infections such as the soil-transmitted nematodes (ascariasis, hookworms, trichuriasis), schistosomiasis, lymphatic filariasis, onchocerciasis, and dracunculiasis.

Of the 20 major helminth infections of humans, the commonest are the geohelminths. Roundworms, members of the phylum Nematoda, are responsible for an estimated 1 billion or more human infections. In many low-income countries, it is more common to be infected than not. Indeed, a child growing up in an endemic community can be infected soon after weaning, and continue to be infected and constantly re-infected for life.

Global and regional epidemiology

Recent global estimates indicate that more than a quarter of the world's population is infected with one or more helminths. The geographic distribution of roundworms in many tropical and subtropical regions closely parallels socioeconomic and sanitary conditions. In locales where several species of intestinal parasites are found, co-infection with *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworms is common. In low- and middle-income countries, about 1.2 billion people are infected with the roundworm, *A. lumbricoides*, while more than 700 million are infected with hookworm (*Necator americanus* or *Ancylostoma duodenale*) or whipworm (*T. trichiura*) (Hotez et al. 2004). The GBD 2010 study estimated that 152,300 people died from neglected tropical diseases, which were predominantly parasitic infections with the

notable exception of rabies (Lozano et al. 2012). While mortality is not common, parasitic infections are responsible for substantial morbidity and indirectly contribute to death from other diseases due to their negative impact on nutritional status.

Issues in presentation

Children of school age are at greatest risk from the clinical manifestations of disease. Studies have shown associations between helminth infection and undernutrition, iron deficiency anaemia, stunted growth, poor school attendance, and poor performance in cognition tests. Some 44 million pregnancies are currently complicated by maternal hookworm infection, placing both mothers and children at higher risk of anaemia and death during pregnancy and delivery. Intense whipworm infection in children may result in trichuris dysentery syndrome, the classic signs of which include bloody diarrhoea, anaemia, growth retardation, and occasionally rectal prolapse. Heavy burdens of both roundworm and whipworm are associated with protein energy malnutrition and deficiencies of certain micronutrients such as vitamin A.

Medical treatment

The WHO recommends the use of albendazole, mebendazole, pyrantel pamoate, and levamisole (Table 8.11.16). The benzimidazoles, albendazole and mebendazole, have high efficacy against roundworm and moderate efficacy against whipworm. Single-dose mebendazole is much less effective against hookworm, with cure rates typically below 60 per cent.

Preventive measures

Better sanitation reduces soil and water transmission as transmission of geohelminths depends on transmission in environments contaminated with egg-carrying faeces. The provision of adequate sanitation is the only definitive intervention to eliminate helminthic infections, but to be effective it should cover a high percentage of the population. With high costs involved, implementing this strategy is difficult where resources are limited. Both the World Bank and the WHO promote helminth control programmes and consider it as one of the most cost-effective strategies to improve health in developing countries. These programmes emphasize mass drug administration as a major component of control.

Recommended drugs for use in public health settings include albendazole (single dose: 400 mg, reduced to 200 mg for children between 12 and 24 months), mebendazole (single dose: 500 mg), and levamisole or pyrantel palmoate. Programmes aim for mass treatment of all children in high-risk groups (communities where worms are endemic) with antihelminthic drugs every 3–6 months. A systematic review of randomized controlled trials found that deworming increases haemoglobin by 1.71 g/L (95 per cent confidence interval 0.70–2.73), which could translate into a small (5–10 per cent) reduction in the prevalence of anaemia (Gulani et al. 2007).

Home delivery of antihelminthics is problematic for several reasons and thus school-based deworming programmes are preferred. These have been shown to boost school participation and are practical as schools offer a readily available, extensive, and sustained infrastructure with a skilled workforce that can be readily trained. In Kenya, such a programme reduced school absenteeism by a quarter, with the largest gains among the youngest children. Perhaps even more importantly, this study showed that those children who had not been treated benefited

Table 8.11.16 Diagnosis and treatment of major intestinal nematode infections

Organism	Type of specimen	Specimen preparation	Size of eggs or larvae (µm)	Drug of choice	Alternative therapies
<i>Trichuris trichiura</i>	Stool	Direct smear or concentration	50–54 × 23	Mebendazole, 100 mg orally (PO) twice daily (bid) × 3 days	Albendazole, 400 mg PO once
<i>Ascaris lumbricoides</i>	Stool	Direct smear or concentration	45–70 × 35–50	Mebendazole, 100 mg PO bid × 3 days or albendazole, 400 mg PO once or pyrantel pamoate, 11 mg/kg PO once (max 1 g)	Piperazine citrate, 75 mg/kg twice daily (max. 1 g) by nasogastric tube × 2–3 days until resolution of obstruction
<i>Ancylostoma duodenale</i> <i>Necator americanus</i>	Stool	Direct smear or concentration	55–70 × 35–45	Mebendazole, 100 mg PO twice daily × 3 days	Albendazole, 400 mg PO once or pyrantel pamoate, 11 mg/kg PO × 3 days (max. 1 g)
<i>Enterobius vermicularis</i>	Adhesive tape preparation	Direct microscopy	50–60 × 20–30	Mebendazole, 100 mg PO once or pyrantel pamoate, 11 mg/kg PO once Repeat in 2 weeks	Albendazole, 400 mg PO once Repeat in 2 weeks
<i>Strongyloides stercoralis</i>	Stool, duodenal aspirate	Concentration or Baermann method	400–500 × 15	Ivermectin, 150–200 micrograms/kg PO × 1–2 days ^a	Albendazole 400 mg PO once or twice daily for 3 days

^a Intrarectal ivermectin is an option for treatment of high-grade strongyloidiasis.

from the generally lowered transmission rate in the schools. These school-based programmes have resulted in improvements in overall nutritional status, growth, physical fitness, appetite, anaemia, and cognitive development. These measures must be coupled with community behaviour change strategies with the aim of reducing contamination of soil and water by promoting the use of latrines and hygienic behaviour. Without a change in defecation habits, periodic deworming cannot attain a stable reduction in transmission.

Prions

Prion diseases, which are also known as transmissible spongiform encephalopathies (TSEs), are responsible for rapidly progressive, fatal neurodegenerative diseases of humans and several other mammalian species. The term 'prion' is derived from *proteinaceous* and *infectious*. An unconventional transmissible protein that lacks nucleic acid is the probable cause; this prion protein appears to consist of a modified isoform of a normal cellular prion protein (PrP^C) that is converted into PrP^{Sc}, which results in major changes in the physicochemical properties of the PrP leading to abnormal folding of normal cellular proteins. Prion diseases are associated with pathology of the brain characterized by diffuse spongiform degeneration. The transmissibility was established by intracerebral inoculation of various primate species using passaged prions from infected humans.

Epidemiology

Human prion diseases can be sporadic, inherited, or transmissible. The sporadic forms include kuru where infection occurs through ritualistic cannibalism and sporadic Creutzfeldt–Jakob disease (CJD). CJD can also occur in a familial manner due to germ-line mutations in the PrP gene or as a result of infection from bovine prions (variant CJD (vCJD)). The TSEs include bovine spongiform encephalopathy (BSE) in cattle; scrapie in sheep; chronic wasting diseases in deer, elk, and mules; feline spongiform encephalopathy in cats (possibly secondary

to ingestion of prion-contaminated bovine tissues and bone meal); transmissible mink encephalopathy; and exotic ungulate encephalopathy in kudu, nyala, and oryx (Ramasamy et al. 2003).

The major forms in human are sporadic CJD, vCJD, and an inherited form, the prion disease called Gerstmann–Straussler–Scheinker disease. Iatrogenic CJD can also occur as a result of infected dura mater grafts, improperly sterilized depth electrodes, transplanted corneas, and human growth hormone and gonadotrophin derived from cadaveric pituitaries.

An epidemic of BSE in the United Kingdom that began in 1986 affected nearly 200,000 cattle and was followed by human cases of vCJD starting in 1994 (Brown et al. 2001). The source of the BSE outbreak resulted from a change in the process of rendering carcasses of livestock, which were used as a protein-rich nutritional supplement for feeding ruminants and other animals. Banning the use of meat and bone meal helped to eventually control the epidemic of BSE. In the mid 1990s, the United Kingdom saw a rise in human vCJD cases with 87 definite or probable case occurring there by November 2000 and a few cases identified as well in France and Ireland. Since the incubation period of vCJD is not known, it was hypothesized to be as short as 5–10 years if the BSE outbreak in the mid to late 1980s was the source. Between 2000 and 2005, the number of annual deaths due to vCJD gradually declined. In total there were 176 cases between 1995 and 2011 in the United Kingdom and 49 recorded in 11 other countries.

Clinical manifestations

Classic CJD usually presents in the elderly (median age of onset 68 years) and is characterized by dementia with the early onset of neurological signs. Death usually occurs within 4–5 months. In contrast, vCJD presents at a median age of 27 years, has an illness duration of 13–14 months, and is clinically characterized by prominent behavioural and psychiatric symptoms, painful dysaesthesias, and the delayed onset of neurological signs.

Table 8.11.17 Public health interventions and their effect on diseases

Major intervention	Disease prevented or treated
Effective antenatal care	Neonatal sepsis and meningitis, pneumonia
Skilled maternal and neonatal care	Neonatal sepsis and meningitis, neonatal tetanus
Maintenance of good personal hygiene	Neonatal sepsis and meningitis, diarrhoea, typhoid fever
Antimicrobial therapy	Neonatal sepsis, meningitis, bacteraemia, diarrhoea, pneumonia, typhoid fever, malaria, parasitic diseases
Vaccines	Pneumonia, typhoid fever, meningitis, bacteraemia
Oral rehydration therapy	Diarrhoea
Vitamin A	Diarrhoea, measles, malaria
Zinc	Diarrhoea, pneumonia, malaria
Provision of safe water, sanitation, and hygiene	Neonatal sepsis and meningitis, diarrhoea, pneumonia, typhoid fever, intestinal helminths
Breastfeeding	Neonatal sepsis and meningitis, diarrhoea, pneumonia
Complementary feeding	Neonatal sepsis, diarrhoea, pneumonia
Intermittent preventive therapy in pregnancy	Malaria
Insecticide-treated nets	Malaria
Integrated vector control	Malaria, dengue, other vector-borne diseases

In addition, vCJD cases all are homozygous for methionine at codon 129 of the PrP gene and have marked accumulation of protease-resistant PrP in brain tissue and florid plaques on neuropathology in large numbers in contrast to classic CJD where these are rare to absent.

Diagnosis and treatment

Neuropathological evaluation by Western blot or immunohistochemistry is the definitive approach for diagnosing human prion diseases. This method can also be used to monitor for vCJD and other forms of CJD. Electroencephalography (EEG) and magnetic resonance imaging (MRI) may be useful adjuncts to diagnosis in patients with CJD. Periodic sharp waves on EEG are often present in classic CJD but absent in vCJD whereas the ‘pulvinar sign’, an abnormal signal in the posterior thalami on T2- and diffusion-weighted MRI images, is present in the majority of patients with vCJD but is rare or absent in CJD.

There is no known therapy for any of the prion diseases. Prognosis is poor with progression to death in a median of 4–5 months for CJD and a little over a year for vCJD.

Conclusion

The global burden of infectious diseases contributing to childhood and adult morbidity and mortality is considerable. The situation is further compounded by increasing antimicrobial resistance and the emergence of new viral infections such as avian influenza (H5N1) and the coronavirus responsible for severe acute respiratory syndrome (SARS). Although the contribution of neonatal infections to overall child mortality has only recently been recognized, the persistent global burden of deaths due to diarrhoea and pneumonia underscore the need for improved public health strategies for change. There are interventions that can make a difference to childhood and adult infectious

diseases (Table 8.11.17). What is needed is their implementation at scale to populations at greatest risk. This will require not only biomedical approaches but also measures to address the social determinants of disease.

Sexually transmitted infections

Mary L. Kamb and Patricia J. Garcia

Introduction to sexually transmitted infections

Sexually transmitted infections (STIs) refer to a broad array of pathogens that are transmitted through vaginal, anal, or oral sex. More than 30 organisms and as many syndromes are recognized as transmissible through sexual contact (Table 8.12.1). However, the vast majority of STIs today are caused by a small number of pathogens, including: three bacterial STIs, chlamydia (*Chlamydia trachomatis*), gonorrhoea (*Neisseria gonorrhoeae*), and syphilis (*Treponema pallidum*); a parasitic infection causing trichomoniasis (*Trichomonas vaginalis*); several viral infections including human papillomavirus (HPV), genital herpes usually caused by herpes simplex virus type 2 (HSV-2) and less commonly HSV-1; three unrelated viruses causing hepatitis: hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV); and human immunodeficiency virus (HIV). The bacterial STIs and trichomoniasis are curable with readily available antibiotic drugs, although previous infection confers no immunity and thus exposed individuals are susceptible to reinfection. In contrast, the viral STIs are not cured with antimicrobial agents and, although symptoms can often be ameliorated with antiviral medications, tend to cause lifelong (prevalent) infections—although some infections can be transient (e.g. with HPV and HBV). Three viral infections (HPV, HBV, HAV) are preventable with vaccines.

STIs are among the world's most common contagious diseases, with the global annual incidence of curable STIs estimated by the World Health Organization (WHO) at just under 500 million cases per year (WHO 2008). Thus, in terms of global burden, curable STIs are exceeded only by diarrhoeal diseases, malaria, and lower respiratory infections. In countries with active notifiable disease surveillance systems, STIs are typically among the most common reportable conditions. For example, in the United States in 2010, laboratory-defined chlamydia and gonorrhoea were the first and second most commonly reported conditions out of more than 50 notifiable diseases, with syphilis ranking fourth (after salmonellosis) (Centers for Disease Control and Prevention (CDC) 2010). However, the burden of curable STIs is dwarfed in comparison to the viral infections. For example, an estimated 290 million women worldwide are HPV carriers (de Sanjosé et al. 2007) and available data support that roughly equal numbers of men are HPV infected

(Dunne et al. 2006; Smith et al. 2011). Globally about 540 million reproductive-aged men and women are infected with HSV-2 (Looker et al. 2008). Although the majority of the world's 360 million HBV infections are transmitted vertically from mother to child, a large number of HBV infections were transmitted sexually; and while most infections are self-limited, a proportion will become chronic infections with potential to lead to severe liver disease and death (CDC 2007). Additionally, approximately 34 million people worldwide are living with HIV infections, of which about 90 per cent were transmitted sexually (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2011).

The majority of STIs are asymptomatic, and thus screening asymptomatic people at risk for STI is as essential a component of effective prevention and control programmes as clinical examination and diagnostic tests in symptomatic disease. Nonetheless, many STIs are associated with disagreeable symptoms such as genital sores, discharges, or rashes that lead affected individuals to seek healthcare services. Given the high numbers of STIs that exist in almost every nation, it is not surprising to find that regardless of a nation's resources, STI symptoms can account for a large number of healthcare visits and substantial costs (Over and Piot 1996; Dallabetta et al. 2007; Owusu-Edusei et al. 2013). Highly stigmatized across all cultures, STIs may also result in psychosocial consequences such as anxiety, shame, disrupted relationships, and even intimate partner violence (Gottlieb et al. 2014). Additionally, the costs and impact of STI-associated health outcomes due to infertility, adverse pregnancy outcomes, malignancies, and HIV acquisition and transmission are increasingly recognized (Owusu-Edusei et al. 2013; Gottlieb et al. 2014). While STI case rates are highest in adolescents and young adults, the most serious health outcomes occur later in life and are disproportionately borne by women and infants. For these reasons, STI prevention and control is an important public health investment for every country.

In this chapter we summarize the global epidemiology of STIs and their associated health consequences, and report on factors affecting STI spread in the community. We also discuss STI prevention and control as a public health intervention, relying on many interrelated interventions working together to reduce STI incidence and prevalence in the community. Finally, we consider some of the most likely challenges and opportunities in STI prevention anticipated over the next few decades.

Table 8.12.1 Sexually transmitted pathogens and associated diseases or syndromes

Pathogen	Associated disease or syndrome
Bacteria	
<i>Neisseria gonorrhoeae</i>	<p><i>Adult:</i> cervicitis, urethritis, proctitis, pharyngitis, Bartholinitis, endometritis, pelvic inflammatory disease (PID), infertility, chronic pelvic pain, orchitis, epididymitis, urethral stricture, prostatitis, perihepatitis, disseminated infection, Reiter's syndrome, enhanced HIV risk, often asymptomatic (up to 2/3 women, 1/3 men)</p> <p><i>Maternal:</i> ectopic pregnancy, maternal death, preterm rupture of membranes</p> <p><i>Infant:</i> neonatal conjunctivitis, corneal scarring, blindness, premature birth, low birth weight (LBW)</p>
<i>Chlamydia trachomatis</i>	<p><i>Adult:</i> cervicitis, urethritis, proctitis, pharyngitis, Bartholinitis, endometritis, PID, infertility, chronic pelvic pain, orchitis, epididymitis, urethral stricture, prostatitis, perihepatitis, disseminated infection, Reiter's syndrome, lymphogranuloma venereum (LGV)—anogenital ulcer or inguinal swelling, enhanced HIV risk, often asymptomatic (up to 2/3 women, 1/3 men)</p> <p><i>Maternal:</i> ectopic pregnancy, maternal death, preterm rupture of membranes</p> <p><i>Infant:</i> neonatal conjunctivitis, pneumonia, premature birth, LBW</p>
<i>Mycoplasma hominis</i>	<i>Adult:</i> postpartum fever, PID
<i>Mycoplasma genitalium</i>	<i>Adult:</i> urethritis, cervicitis, PID, enhanced HIV risk
<i>Ureaplasma urealyticum</i>	<p><i>Adult:</i> urethritis</p> <p><i>Maternal:</i> chorioamnionitis, premature delivery</p> <p><i>Infant:</i> premature birth, LBW</p>
<i>Treponema pallidum</i> (syphilis)	<p><i>Adult:</i> genital ulcer (chancres), local adenopathy, skin rashes, condyloma lata, hepatitis, arthritis, enhanced HIV risk; bone, cardiovascular (e.g. aortic disease) and central nervous system disease (e.g. meningitis, stroke, cranial nerve abnormalities, optic atrophy, tabes dorsalis, general paresis)</p> <p><i>Maternal:</i> fetal loss, stillbirth, preterm delivery</p> <p><i>Infant:</i> neonatal death, congenital syphilis, LBW</p>
<i>Gardnerella vaginalis</i> (in association with other bacteria)	<p><i>Adult:</i> bacterial vaginosis, PID, enhanced HIV risk, urethral discharge</p> <p><i>Maternal:</i> chorioamnionitis, prematurity, LBW</p>
<i>Haemophilus ducreyi</i> (chancroid)	<i>Adult:</i> genital ulcers, inguinal adenitis, disfiguring lesions, tissue destruction, enhanced HIV risk
<i>Calymmatobacterium granulomatis</i> (Donovanosis)	<i>Adult:</i> Nodular swellings and ulcerative lesions of inguinal and anogenital areas (also called granuloma inguinale)
<i>Shigella</i> spp.	<i>Adult:</i> shigellosis in homosexual men
<i>Salmonella</i> spp.	<i>Adult:</i> enteritis, proctocolitis in homosexual men
<i>Campylobacter</i> spp.	<i>Adult:</i> enteritis, proctocolitis in homosexual men
Viruses	
Human immunodeficiency virus types 1 and 2	<p><i>Adult:</i> HIV-related disease, opportunistic infections, lymphomas, AIDS</p> <p><i>Maternal:</i> vertical transmission to infants</p> <p><i>Infant:</i> HIV infection</p>
Herpes simplex virus types 1 and 2	<p><i>Adult:</i> anogenital vesicular lesions and ulcerations, recurrent genital ulcers, cold sores, cervicitis, urethritis, pharyngitis, proctitis, chronic pain, arthritis, aseptic meningitis, hepatitis, enhanced HIV risk</p> <p><i>Maternal:</i> vertical transmission to infants</p> <p><i>Infant:</i> ulcerations of skin, eye, mucous membranes; encephalitis, disseminated infection with hepatitis, pneumonitis, encephalitis; neurological abnormalities</p>
Human papilloma virus (> 30 genital genotypes identified)	<p><i>Adult:</i> anogenital and oral warts; intraepithelial neoplasia and carcinoma of the cervix, penis, vulva, vagina, anus; oropharyngeal cancer; recurrent respiratory papillomatosis</p> <p><i>Maternal:</i> vertical transmission to infant</p> <p><i>Infant:</i> recurrent respiratory papillomatosis</p>
Hepatitis B virus	<p><i>Adult:</i> acute hepatitis, liver cirrhosis, end-stage liver disease, hepatocellular cancer</p> <p><i>Maternal:</i> vertical transmission to infant</p> <p><i>Infant:</i> cirrhosis, end-stage liver disease, primary liver cancer</p>
Hepatitis A virus	<i>Adult:</i> acute hepatitis A
Hepatitis C virus	<i>Adult:</i> acute hepatitis C, liver cirrhosis, end-stage liver disease, hepatocellular cancer

(continued)

Table 8.12.1 Continued

Pathogen	Associated disease or syndrome
Cytomegalovirus (CMV)	Adult: heterophil-negative infectious mononucleosis, hepatitis Infant: primary infection of the newborn, hepatitis, sepsis, deafness, mental retardation
Molluscum contagiosum virus	Adult: genital molluscum contagiosum
Human T-lymphotrophic retrovirus, type 1	Adult: human T-cell leukaemia or lymphoma
Human herpesvirus 8 (HHV-8)	Adult: Kaposi's sarcoma, primary effusion lymphoma, Castleman's disease
Protozoa	
<i>Trichomonas vaginalis</i>	Adult: vaginitis, cervicitis, urethritis, endometritis, salpingitis, enhanced HIV risk Maternal: chorioamnionitis, preterm delivery Infant: LBW, pneumonitis, fever, vaginal discharge in female infants
<i>Entamoeba histolytica</i>	Adult: amoebiasis in men who have sex with men
<i>Giardia lamblia</i>	Adult: giardiasis in men who have sex with men
Fungi	
<i>Candida albicans</i>	Adult: vulvovaginitis, balanitis
Ectoparasites	
<i>Phthirus pubis</i>	Adult: pubic lice infestation
<i>Sarcoptes scabiei</i>	Adult: scabies, Norwegian (disseminated) scabies Infants: Norwegian (disseminated) scabies

Global burden of sexually transmitted infections

The global burden of STIs includes overall numbers of infection, a host of short- and long-term adverse health outcomes causing morbidity and mortality in individuals, and the financial consequences (healthcare and other costs) associated with STIs and their associated health impact for both individuals and economies.

Global STI numbers

The WHO estimated that in 2008, approximately 499 million new cases of curable STIs occurred among men and women aged 15–49, including 106 million cases of chlamydia, 106 million cases of gonorrhoea, 11 million cases of syphilis, and 276 million cases of trichomoniasis (WHO 2008). New cases of STIs were common in all regions of the world, particularly the highly populated regions of the Americas (comprising the countries of North and South America and the Caribbean), East Asia and the Western Pacific, and South and Southeast Asia; however, rates were highest in the sub-Saharan Africa region (24 cases per 100 adults) and the region of the Americas (26 cases per 100 adults) (Fig. 8.12.1). Because population-based studies and active, laboratory-based reporting are limited in many countries, methodologies for estimating global STIs have been based on discrete, representative (but typically small) studies and good case-based surveillance reports contributed by countries in each region, with adjustment for unreported and undiagnosed cases (WHO 2008). The availability of such studies and reports and the methodological criteria used for including or excluding studies have varied over time, and thus assessing trends in estimates is somewhat challenging. However, comparing the 2008 global STI estimates to the most

recent prior report (2005), which used a similar methodology, suggests there has been limited if any recent improvement; in fact STI numbers are likely rising. Specifically, there was no observable change in syphilis numbers, a modest (4 per cent) increase in chlamydia cases, and larger increases in trichomonas (11 per cent) and gonorrhoea (21 per cent) cases.

All regions of the world observed increased numbers of curable STIs, supporting the case that global STI burden is indeed increasing. Increases were particularly notable in the region of the Americas and the Eastern Mediterranean region (i.e. countries of Northern Africa and the Middle East) where overall STI numbers more than doubled. While some of the increased numbers could be attributed to an increasing population, case rates of curable STI cases per 100 adults also rose in most regions—most notably in the Americas where they almost doubled between 2005 and 2008. More modest increases in case rates were observed in the Eastern Mediterranean region and in the two Asian regions; and STI case rates did not change appreciably in sub-Saharan Africa or Europe. It is possible that some of the observed increases in curable STI case numbers and rates globally were due to differences in screening practices among countries included in the report. However, reported screening practices seemed to be fairly similar across the two time periods (personal communication, WHO). Some of the increases could be attributable to broader availability of highly sensitive diagnostics (e.g. nucleic acid amplification tests (NAATs)) in some settings, as the extent to which curable STIs are asymptomatic has been relatively recently appreciated with increasingly sensitive diagnostics. However, in 2008 use of NAATs was still limited outside Europe and North America, and the vast majority of curable STIs occurred in low- and middle-income countries (WHO 2008). Additional data supporting that global

Fig. 8.12.1 Estimated annual numbers and incidence per 100 adults of curable STIs among men and women aged 15–44 years in 2008, by WHO region. Curable STIs include gonorrhoea, chlamydia, syphilis, and trichomoniasis. In 2008, approximately 499 million cases of curable STIs occurred globally among reproductive-aged adults. Source: data from World Health Organization (WHO), Department of Reproductive Health and Research, *Global incidence and prevalence of selected curable sexually transmitted infections—2008*, Copyright © WHO 2012, available from http://apps.who.int/iris/bitstream/10665/75181/1/9789241503839_eng.pdf

burden of STIs is likely not declining comes from surveillance systems in Europe and North America, in the context of established national STI control programmes: although marked declines in syphilis and gonorrhoea case rates occurred in the past, recently trends have tended to be stable.

One problem faced by the research team conducting the 2008 estimates was identifying appropriate studies for inclusion. Many national STI reporting systems are based on syndromic management, and thus STI-specific aetiology is unknown (Gottlieb et al. 2014). In some regions, such as Latin America, underreporting of STIs is common, and there is not yet consensus on which STIs to report or how to report data, resulting in burden of disease estimates that may not reflect the true situation (Garcia et al. 2011). Also notable, the authors of the most recent WHO STI estimates observed that the number of studies that met entry criteria had decreased remarkably over the 3-year interval between the 2005 and 2008 estimates, from 402 data points to 180 data points, respectively (WHO 2008). They reported that possible reasons for this included fewer studies being done in the general population, journals less interested in publishing STI surveillance data, and longer publication lead times. Public health funding focused on STIs other than HIV has also dwindled over that time interval, probably contributing to the decreasing availability of reliable STI prevalence data.

The 2008 global STI estimates evaluated curable STIs and did not attempt to estimate the extent of new and prevalent viral infections, which is difficult to estimate but easily exceeds a billion infections. For example, a 2007 review of genital HPV, arguably the most common STI, estimated that approximately 10 per cent of women worldwide had HPV infections at any point in time (de Sanjosé et al. 2007). Furthermore, US longitudinal studies

suggest that as many as 50–70 per cent of sexually active participants had evidence of an HPV infection at some point in their lives (Weinstock et al. 2004; Baseman and Koutsky 2005), and estimated that the virus accounted for about 5 million new infections annually in the United States alone (Weinstock et al. 2004; Baseman and Koutsky 2005). The vast majority of HPV infections are latent or asymptomatic and will not lead to overt disease or important health consequences. However, up to one-third of HPV infections globally are caused by oncogenic types (primarily types 16 and 18) with potential to lead to anogenital cancers, mainly occurring in low- and middle-income countries (de Sanjosé et al. 2007).

Vying with HPV in numbers is HSV-2, the agent most frequently associated with genital herpes. HSV-2 is exceedingly common, with reported population prevalences among nations ranging from 20 to 40 per cent or even higher, the vast majority of infections being asymptomatic (Smith and Robinson 2002). A 2003 systematic review estimated that worldwide, 536 million people aged 15–49 years were living with HSV-2, of whom 23.6 million were newly infected that year (Looker et al. 2008). National data are lacking in most countries. Based on 1999–2004 US national population-based surveys, about 17 per cent of reproductive-aged adults were HSV-2 infected, with prevalence increasing with advancing age (e.g. from 1.6 per cent in 14–19-year-olds up to 26.3 per cent in 40–49-year-olds) (Smith and Robinson 2002; Xu et al. 2006). In those surveys, HSV-2 prevalence varied considerably by race/ethnicity, with non-Hispanic black people having almost three times higher HSV-2 prevalence compared with other racial/ethnic groups (Xu et al. 2006). An important aspect of HSV infection is its clinical synergy with HIV; in co-infection each virus enhances shedding of the other. This phenomenon has led in turn

to a population-level synergy: countries with rising HIV prevalence have reported increasing HSV-2 prevalence, suggesting that in the absence of effective prevention strategies a vicious cycle occurs with increasing prevalence of both infections (Paz-Bailey et al. 2007).

At least five distinct viruses are known to cause viral hepatitis (an acute illness characterized by nausea, malaise, abdominal symptoms, and jaundice), of which three (unrelated) viruses are common: hepatitis A, hepatitis B, and hepatitis C (CDC 2009). All three viruses are able to be transmitted sexually, although that is not their usual mode of spread. The majority of the world's 360 million chronic HBV infections were transmitted vertically from mother to child, although a substantial minority were related to injecting drug use (IDU) or other parenteral exposure including iatrogenic exposures through procedures such as haemodialysis or blood transfusion, or through sexual contact (WHO 2012a, 2014). Among US cases of HBV reported in 2007, 38 per cent had multiple sex partners, 11 per cent were men who had sex with men (MSM), and 6 per cent had sexual contact with a person known to have hepatitis B (CDC 2009). HCV, estimated at about 150 million chronic infections worldwide, is primarily transmitted through percutaneous exposures such as IDU or iatrogenic exposures, although it can also be transmitted through mucosal exposure with an infected person (e.g. through sexual activity) (WHO 2012a). Of the US cases of HCV reported in 2007 and for which risk factor information was available, IDU was the most commonly identified risk factor reported by 44 per cent of cases; 42 per cent reported multiple sex partners, 20 per cent reported having had surgery, and 10 per cent reported having sexual contact with a person known to have HCV (CDC 2009). Hepatitis A virus (HAV) is transmitted through faecal–oral contact. Among the most frequently identified risks are sexual and household contact with an HAV-infected person; accounting for about 8 per cent of reported cases in the United States (CDC 2009). The virus can be transmitted during sexual activity, and in the United States outbreaks in MSM have been linked to rectal–oral mucosal exposures during sex (CDC 2009). Risk factors for all three of the common hepatitis viruses likely vary considerably among countries depending upon prevalence of specific injecting and sexual practices, quality control of clinical procedures, and access to and availability of preventive services (e.g. vaccines against HAV and HBV, appropriately sterilized medical equipment, clean needles, condoms, education).

In addition to affecting adults, STIs can be transmitted from mother to child *in utero* or at the time of delivery. In 2011, UNAIDS estimated that 330,000 children acquired HIV infection, predominantly through perinatal transmission or contaminated breast milk (UNAIDS 2012). This represented a 43 per cent decline in new infections since the peak of the HIV pandemic in 2003, indicating effectiveness of prevention of mother-to-child transmission (MTCT) of HIV screening and treatment programmes. More than 90 per cent of perinatal HIV infections have occurred in sub-Saharan Africa (UNAIDS 2011, 2012). Less well recognized than MTCT of HIV is the contribution of maternal syphilis infection during pregnancy on global perinatal morbidity and mortality. A WHO report using a health service delivery model and universal access data for HIV and syphilis calculated that, worldwide in 2008, 1.36 million pregnant women had syphilis infections capable of transmitting *Treponema pallidum* perinatally

(Newman et al. 2013). In 2008, untreated maternal syphilis infections resulted in an estimated 521,000 adverse health outcomes in infants, ranging in severity from stillbirth or neonatal death to congenital infection in live born infants (Newman et al. 2013). Other STIs such as HSV-2 and cytomegalovirus (CMV) can be transmitted from mother-to-child *in utero*; however, global data are limited and country-specific data indicate these are substantially less common than perinatal HIV or syphilis (Xu et al. 2008).

STI-associated morbidity

Many individuals acquiring a new STI suffer disturbing physical symptoms, ranging from relatively minor discomfort or cosmetic concerns to intensely painful and recurrent conditions. Acquiring an STI may also result in psychological harm such as intense anxiety, shame, fear of disclosing to sex partners, or disrupted relationships (Cunningham et al. 2002; WHO 2007). A link between intimate partner violence and HIV has been well documented, and increasingly literature suggests that other STI diagnoses can be associated with intimate partner violence (Decker et al. 2011; Swartzendruber et al. 2012). Additionally, stigma or shame about an STI diagnosis may result in delays in health seeking and lack of full disclosure or discussion with health providers and sex partners (Cunningham et al. 2002; Fortenberry et al. 2002). This situation limits the effectiveness of both case management and partner management, and can increase likelihood of individual morbidity as well as further disease spread in the community.

In addition to short-term symptoms, many STIs are associated with long-term or chronic health problems (Table 8.12.1). Longer-term STI-associated health consequences have been broadly categorized into four areas: female reproductive health disorders (e.g. infertility, ectopic pregnancy, chronic pelvic pain); adverse pregnancy outcomes (e.g. stillbirth, neonatal death, prematurity); malignancies (e.g. anogenital cancers associated with HPV); and enhanced HIV acquisition mediated by ulceration or mucosal inflammation and increased numbers of HIV target cells associated with certain STIs. Although men are as likely, and in some settings more likely, than women to become infected with a new STI, women and infants bear the brunt of the longer-term STI-associated morbidity such as tubal factor infertility, adverse pregnancy outcomes, and cervical cancers. Exceptions to this are HBV-associated chronic liver disease and malignancy and enhanced risk for HIV infection which affect large numbers of men as well as women.

The most common of the serious STI consequences are adverse reproductive outcomes, particularly infertility, often caused by chlamydia and gonorrhoea. Chlamydia and gonorrhoea are highly prevalent infections, and from 10 to 40 per cent of women with untreated infection may develop pelvic inflammatory disease (PID)—an inflammation of the upper female tract that can manifest as endometritis, salpingitis, tubo-ovarian abscess, pelvic peritonitis, or some combination of these (CDC 2010). Up to 25 per cent of affected women are reported to experience infertility (Fortenberry et al. 2002; WHO 2007a). Tubal scarring may lead to ectopic pregnancy, associated with maternal morbidity and mortality as well as pregnancy loss. Women with a prior history of PID have been reported to be six to ten times more likely than unaffected women to develop a subsequent ectopic pregnancy; and an estimated 40–50 per cent of all ectopic pregnancies have been attributed to PID (CDC 2010). Chlamydial and gonorrhoeal

infections also can lead to chronic pelvic pain in women. Trichomoniasis, the most common curable STI, primarily causes vaginal discharge in women although is typically asymptomatic in men. Vaginal discharge syndrome can be notoriously difficult to manage and may lead to multiple, costly healthcare visits, particularly in resource-poor settings without laboratory capacity to support aetiological diagnosis allowing targeted treatment with appropriate antimicrobial agents (Ryan et al. 2008).

Several STIs are associated with adverse pregnancy outcomes affecting the health or viability of infants. Perhaps the most devastating is maternal syphilis infection in pregnancy. Historical literature reported that untreated primary or secondary infections typically led to fetal death (Fiumara 1988); and that even latent infections of several years' duration could lead to complications if left untreated (Fiumara 1988). In a 2013 meta-analysis of the published literature that adjusted for other causes of poor pregnancy outcomes, untreated maternal syphilis infection resulted in seriously adverse pregnancy outcomes in over 50 per cent of cases (Gomez et al. 2013). Among untreated mothers, poor outcomes included stillbirth or fetal loss (21 per cent), neonatal death (9 per cent), prematurity or low birth weight (6 per cent), or an infected infant (15 per cent) (Gomez et al. 2013). The WHO estimated that, globally in 2008, two-thirds of syphilis-related adverse pregnancy outcomes were in women who were not tested or treated for syphilis during their pregnancies (Newman et al. 2013). Maternal infection with chlamydia during pregnancy has been associated with neonatal pneumonia and more commonly with neonatal conjunctivitis which, if left untreated, can lead to blindness. WHO estimated that in 2006, from 1000 to 4000 infants worldwide were blinded from STI-related conjunctivitis, although it is easily preventable with topical antimicrobial agents (WHO 2007a). Numerous observational studies have found an association between *T. vaginalis* infection and premature birth, although high-quality studies assessing this are limited (WHO 2007a; CDC 2010). However, some studies of *T. vaginalis* treatment during pregnancy found treatment associated with higher risks of poor pregnancy outcomes (Klebanoff et al. 2001; Kogozi et al. 2003). In addition to the well-recognized complications of HIV, other viral STIs can also cause adverse pregnancy outcomes. HSV-2 can cause neonatal herpes infection which, although unusual (estimated at one in 3000 births in the United States), is often severe or fatal when primary infection occurs during pregnancy (Brown et al. 1997; Dinh et al. 2008; Xu et al. 2008). Perinatally transmitted HPV can cause recurrent respiratory papillomatosis, a chronic condition often requiring recurrent surgical procedures. For perinatally acquired HBV, about 30 per cent will result in chronic infection, of which a portion will go on to serious complications including cirrhosis, liver failure, hepatocellular carcinoma, and death (CDC 2009).

Among the most serious complications associated with STI are certain malignancies, typically occurring after a latent period of many years or decades after the initial exposure and, therefore, often not recognized as related to an STI. STI-associated malignancies include anogenital cancers associated with oncogenic HPV types, hepatocellular carcinoma (primary liver cancer) associated with chronic HBV infection, some lymphomas associated with HIV and Kaposi's sarcomas associated with human herpes virus type 8 (HHV-8). The WHO estimates that up to 20 per cent of all cancers are related to the sexually transmitted viruses HPV

and HBV alone, and this proportion is higher in low-income nations (WHO 2013). For HPV, it has been firmly established that certain specific subtypes are the causal agents of cervical cancer, and likely of other anogenital cancers (e.g. vulvar, vaginal, penile, anal) as well (Zur Hausen 1996; Coglianò et al. 2005). Two carcinogenic HPV types, 16 and 18, are responsible for an estimated 70 per cent of all cervical cancers and 80 to 90 per cent of anal and penile cancers worldwide (Zur Hausen 1996; Munoz et al. 2003; Coglianò et al. 2005). Cervical cancer is now the second most common cancer in women worldwide, after breast cancer, but is the leading cause of cancer mortality in women in low-income countries and is estimated to account for 275,000 deaths annually worldwide (WHO 2013). The cellular changes associated with oncogenic HPV types occur slowly, presenting with dysplasia and later with localized (*in situ*) disease before proceeding to invasive cancer, a natural history which can allow early detection and treatment through cervical screening programmes (i.e. Pap test or direct cervical visualization). The great disparity in cervical cancer morbidity and mortality between high- and low-income nations has been attributed in large part to limited availability of cervical screening and treatment in poor countries lacking public health infrastructure. Additionally, a significant interaction exists between HPV and HIV which can accelerate HPV-related cellular changes and this likely further contributes to high cervical cancer incidence in poor nations with high HIV prevalence. Routine periodic cervical screening with a Pap test is the standard of care in most high-income and an increasing number of middle-income nations, with more frequent screening intervals recommended for HIV-infected women. However, in low-income nations many women have never had a Pap smear (Paz Soldan et al. 2008). Increased coverage of HPV vaccines has enormous potential to prevent cervical cancer in upcoming generations of women (Gottlieb et al. 2014) and HPV vaccines have proven to be cost-effective in different settings (Goldie et al. 2008, 2012; Campos et al. 2012).

Hepatocellular carcinoma, accounting for 695,000 deaths annually worldwide, is the third most common cause of cancer deaths in adults but ranks higher in some countries in Asia and sub-Saharan Africa (WHO 2013). Globally, just over half of hepatocellular carcinomas are attributed to chronic HBV infection, although regional estimates vary widely, ranging from 16 per cent in North America, about half of all cases in Africa and Southeast Asia, 59 per cent of cases in Eastern Mediterranean countries, and approximately 65 per cent of cases in East Asia (Perz et al. 2006). Another quarter of hepatocellular cancers globally are caused by chronic HCV infection (Perz et al. 2006). In addition to malignancies, HBV and HCV also are major contributors to cirrhosis, each estimated to account for about 30 per cent of all cases globally (Perz et al. 2006). Among the most distressing prevention failures has been the limited uptake of HBV vaccine which has been available since 1982 and has an outstanding record of safety and effectiveness (95 per cent) in preventing infection and its chronic sequelae (WHO 2012a, 2014). However, awareness of the problem and resources for increased vaccination coverage is finally increasing, and by 2011, 179 countries had included infant vaccination against hepatitis B as part of their vaccination schedules.

A fourth broad category of adverse STI-associated outcomes is related to enhanced HIV transmission and acquisition associated with certain STIs, particularly those associated with genital ulcers

(e.g. syphilis, HSV-2, chancroid) or inflammation (e.g. chlamydia, gonorrhoea, trichomoniasis). Studies are clear that STIs are risk factors for both HIV transmission and acquisition (Fleming and Wasserheit 1999; Hay 2008). STI-associated genital ulcer disease was identified as a strong, independent risk factor for HIV acquisition in men (both heterosexual and homosexual) and women in early HIV research studies (Fleming and Wasserheit 1999; Hay 2008). This was also true for STIs associated with inflammation causing cervicitis or urethritis (i.e. chlamydia, gonorrhoea, trichomonas) although HIV risk was somewhat lower than that of genital ulcer disease. In HIV-uninfected people, STIs have been demonstrated to increase the numbers of HIV target cells and possibly impair natural barriers to infection, thus enhancing likelihood of HIV acquisition (CDC 2010). In HIV-infected people, co-infection with some STIs has been found to lead to periods of elevated genital viral load and increased HIV shedding, and thus co-infected individuals are more likely to transmit HIV to an uninfected partner (Cohen et al. 1997; Wang et al. 2001; Cohen 2007). Effective treatment of STI-infected people co-infected with HIV has been demonstrated to lower genital shedding of HIV-1 (Cohen et al. 1997; Ghys et al. 1997; Wang et al. 2001; Cohen 2007). Clearly, prompt detection and effective treatment of STI co-infection (especially those causing genital ulcer disease or mucosal inflammation) is an important HIV prevention intervention at the individual host level.

At the population level, the influence of STI treatment on HIV prevention is muddier. Intervention studies have demonstrated that quality STI case management (i.e. effective STI diagnosis, treatment, condom promotion) can reduce or prevent rise in HIV incidence among high-risk individuals (e.g. female sex workers) (Laga et al. 1994; Levine et al. 1998; Plummer et al. 2005). Additionally, a community randomized trial conducted in rural Tanzania in the early 1990s documented that communities receiving an improved programme of management of symptomatic STI (syndromic case management) had significantly lower HIV incidence than communities with typical STI management programmes, supporting an HIV prevention benefit at the community level (Grosskurth et al. 1995). The lack of a similar effect in subsequent community level intervention trials (i.e. Rakai study of mass treatment (Wawer et al. 1998); Masaka study of enhanced syndromic management (Korenromp et al. 2005)) evaluating various STI control strategies indicated that a community-level HIV benefit does not occur in all circumstances or for all populations. STI treatment for HIV prevention may be particularly important in settings of early (concentrated) epidemics with a high prevalence of curable STIs among 'core groups' (i.e. people with multiple partners at well-connected points in sexual networks who are responsible for continuing STI transmission) (White et al. 2004; Korenromp et al. 2005; Hay 2008). This was a characteristic of early HIV epidemics in Africa, and more recently those of Eastern Europe and Central and East Asia (Galvin and Cohen 2004). It is also a characteristic of epidemics among youth everywhere, making high-risk young people a particularly important subpopulation with whom to focus STI control strategies aimed at HIV prevention.

As noted, STI management may be particularly important in preventing transmission from people with HIV infection, underlining the importance of offering STI services to those in HIV care. The strong association of genital ulcer disease with HIV transmission, along with the earlier noted observation that high

HSV-2 prevalence often occurs in countries with high HIV prevalence, raised the question of whether treatment of genital HSV-2 might reduce the likelihood of HSV-2 or HIV shedding (or both) and thus prevent transmission or acquisition of new HIV infections (Galvin and Cohen 2004; Xu et al. 2006). Thus far this does not seem to be the case. Several large and rigorous multi-national randomized controlled trials evaluating antiviral treatment against HSV were unable to demonstrate benefit in reducing HIV acquisition or transmission (Hayes et al. 2010), perhaps because the herpes treatment provided was unable to adequately reduce inflammation. Mathematical modelling studies continue to suggest the importance of HSV-2 in HIV transmission as HIV epidemics mature (Ward and Rönn 2010), pointing out the potential impact of an effective HSV-2 vaccine should one be able to be developed (Gottlieb et al. 2014).

STI costs

Given the enormous global numbers, the healthcare costs associated with acute STIs and their long-term health consequences are assumed to be substantial in every nation. However, relatively few studies have examined this well. A 1997 Guttmacher Institute brief reported that each year STIs including HIV accounted for 6 per cent of healthy years of life lost among reproductive aged women worldwide, 35 per cent higher than men of the same age (Landry and Turnbull 1998). Among women, PID accounted for 43 per cent of all healthy years lost, followed by HIV (42 per cent), syphilis and gonorrhoea (11 per cent), and chlamydial infection (4 per cent); whereas among men most (82 per cent) STI-related morbidity was due to HIV. Additionally, in 2003 the World Bank calculated that among reproductive-aged women in developing nations, STIs were the third most important cause of years of healthy productive life lost, exceeded only by pregnancy-associated maternal morbidity and HIV (World Bank 2004). An acute STI can impose substantial financial costs on individuals and economies. A 2006 review of STI treatment costs in low- and middle-income nations found the median costs for drugs alone was US\$2.62, more than three times the average daily income in most low-income nations (Terris-Prestholt et al. 2006). This conservative analysis did not take into account indirect costs, such as those related to travel or missing work. A study evaluating the annual direct economic burden of STIs in the United States estimated that the direct medical costs of STIs, excluding HIV, were approximately US\$3 billion in 2008. This estimate did not include direct costs related to cervical cancer screening (estimated at US\$5 billion per year) or adverse pregnancy outcomes, indirect (i.e. productivity loss) or intangible (i.e. pain and suffering, deterioration in quality of life, physical impact on families) costs, or costs related to prevention (Owusu-Edusei et al. 2013).

Transmission of sexually transmitted infections

A number of risk factors have been associated with acquiring a new STI, such as age of sexual initiation, number and type (e.g. primary partner or sex worker) of sex partner, or use of barrier protection (e.g. condoms) to name just a few. In addition to studying risk factors in individuals, it is possible to study the spread of infection within populations. The spread of STIs in a population or 'community' is influenced by a limited number of proximate

biological and behavioural determinants, as well as a wide range of social, economic, demographic, and cultural factors affecting individuals, communities or both (Garnet 2008).

STI transmission dynamics

An important concept in understanding both STI transmission in populations and the potential impact of various prevention strategies is the STI transmission dynamics model of May and Anderson (1987). The reproductive rate of an STI in a population (R_0), that is, the average number of new infections generated by each infected person, is based on three factors: (1) the likelihood of transmission per sexual contact between an infected person and a susceptible partner (β); (2) the average number of new sexual partnerships formed over time between infected and susceptible people (c); and (3) the average duration of infectiousness (D), where $R_0 = \beta cD$. Incidence and prevalence of a specific STI within a population will increase when $R_0 > 1$ and will decrease if $R_0 < 1$. Circumstances that reduce any of the three factors will reduce R_0 and population prevalence (Brunham 2005).

A primary focus of STI prevention programmes has been reduction in duration of infectiousness (D) by detecting and treating infected people. Measures to accomplish this goal include enhancing access to and utilization of quality healthcare, improving case finding, and improving completion of treatment after clinical contact. Prevention strategies that reduce transmission efficiency (β) and number of sexual partnerships (c) can decrease prevalence of all STIs, and could be particularly useful in preventing those that are not curable by antimicrobial therapy, such as HIV, HSV-2, and HPV. In the past most approaches to reduce transmission efficiency were behavioural (e.g. efforts to promote condom use), but an increasing number of prevention trials evaluating efficacy of biomedical interventions have shown encouraging results. For example, suppressive antiviral therapy of HSV-2 and more recently of HIV-1 have been proven to reduce transmission within discordant sexual partnerships (Corey et al. 2005; Cohen et al. 2011). Male circumcision reduces transmission of HIV and other STIs (Weiss 2007). Most importantly, effective vaccines greatly limit susceptibility, and have already substantially reduced the incidence of HBV in developed countries (WHO 2012a, 2014). Results of at least one early study of a population-wide HPV vaccination programme finding significant decreases in high-grade cervical abnormalities in young women suggests that well-implemented HPV vaccination programmes have good potential to prevent anogenital cancers as well as reduce future health costs related to screening and treatment (Brotherton et al. 2011). Finally, strategies to reduce sexual partnerships between susceptible and infected partners have potential for the broadest effects, but are difficult to implement and sustain. For example, although programmes to encourage abstinence by adolescents have been strongly encouraged in the many countries, there is growing evidence that such programmes may have limited effectiveness (Santelli et al. 2006). Encouraging a reduction in the number of sex partners, particularly among people with frequent sex partner change, may be a more plausible approach, based on experiences in several countries where HIV prevalence has fallen (Shelton et al. 2004).

Sexual networks and core groups

Networks of sexual interaction within populations also influence likelihood of contact between susceptible and infected people

(Aral et al. 1996; Adimora and Schoenbach 2005). Sexual networks consist of groups or individuals who are directly or indirectly sexually connected, and the location of an individual in such networks can influence the likelihood of infection as much as or more than personal behaviour by influencing the prevalence of infection in their partners. Larger numbers of sexual linkages in a subpopulation can result in transmission of STI from core groups to the general population, especially if the sexual partnerships are formed concurrently (i.e. two or more partnerships that overlap in time) rather than sequentially, and involve dissassortative (like-with-unlike) mixing patterns (Aral et al. 1996). Sexual networks can be affected by a variety of contextual factors, such as community norms about sexual behaviour; migration and travel patterns; economic circumstances; and the societal disruptions induced by natural disasters, political conflict, and wars. As noted earlier, a related concept in STI prevention is that of the 'core group'. From the perspective of STI transmission determinants, they are defined as groups or individuals with sufficient rates of sex partner change to maintain $R_0 > 1$; and their characteristics will vary by their location in the sexual network and by specific STIs depending on duration of infection and efficiency of transmission. Targeting core groups with STI prevention efforts such as screening and condom promotion can be more efficient and cost-effective than efforts targeted more broadly (Douglas and Fenton 2008). Programmes focusing on sex workers, people living in geographic areas with a high prevalence of reported cases of sexually transmitted disease (STD), incarcerated people, or those with repeat STIs have used the core group approach (Leichliter et al. 2007; Williams and Kahn 2007).

Prevention and control of sexually transmitted infections

For communicable diseases such as STIs, effective diagnosis and treatment is an important prevention strategy. Prompt and effective treatment of curable STIs minimizes their acute symptoms and potential to develop longer term adverse sequelae in the individual patient, and also reduces further spread of the infection into the community (making STI exposure less likely). STI control is not simply STI treatment; many interrelated interventions work together to reduce STI incidence and prevalence (Steen et al. 2009). The concept that clinical management alone has serious limitations is illustrated in Fig. 8.12.2, adapted from a tuberculosis management model developed using actual data from rural women in one African nation (Waalder and Piot 1969;

Fig. 8.12.2 Piot-Fransen model of STI prevalence and typical STI case management. The figure shows the series of steps required to ensure effective STI treatment. In typical STI case management as currently practised around the world, an increasing proportion of STI-infected individuals are missed with each succeeding step.

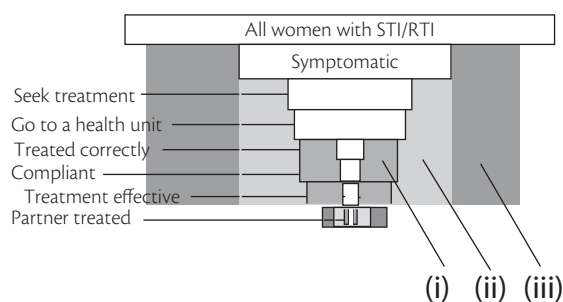

Fig. 8.12.3 Potential benefits of additional control strategies in concert with STI case management. The figure shows the potential expanded coverage of STI case management if various interventions are applied: (i) well-conducted clinic-based case management, which requires symptomatic people seek and obtain effective treatment, (ii) the addition of targeted outreach and community-based programmes that are able to identify and effectively treat most symptomatic STIs in the community, and (iii) the addition of screening of asymptomatic people.

Ryan et al. 2008). Fig. 8.12.2 describes STI prevalence in a community and a series of steps required to ensure effective STI treatment, focusing on the proportion of STIs missed (not effectively treated) at each step. The model illustrates that most people with STIs, even those with symptoms, are not effectively treated; and even fewer have sex partners who are effectively treated. However, these issues can be addressed. Fig. 8.12.3 shows the potential benefits of: (1) well-conducted clinic-based management (i.e. people coming to health facilities, whether public or private, to obtain effective STI treatment); (2) the incremental benefits that might be attained if symptomatic patients who do not come to formal health facilities could be identified and receive STI services (e.g. through pharmacies (Garcia et al. 1998, 2012), asymptomatic screening, targeted outreach programmes, community-based educational efforts and effective partner management); and (3) the incremental benefits that primary prevention might bring (e.g. through high coverage of an effective STI vaccine; or widespread community education around STI prevention, whether abstinence, delaying initiation of sex in adolescents, or promotion of safer sex practices such as correct and consistent condom use). The synergies that can occur with multiple interventions working together was demonstrated in a Peruvian study of a multicomponent intervention including well-conducted STI syndromic management provided by a network of pharmacies and physicians, a mobile-team outreach providing presumptive treatment to female sex workers, along with a condom promotion campaign directed toward young people (Garcia et al. 2012). The combination intervention was able to reduce STIs at the community level, in young adult women and in female sex workers.

From a public health perspective, a comprehensive STI prevention and control programme involves several components working together. One important component is *STI surveillance*, providing the data for programme decision making. Another component is *accessibility of healthcare*, ensuring STI infected people reach case management or other services. Perhaps the most obvious component is *STI case management*, which itself involves an integrated package of prevention and partner services supporting clinical diagnosis and treatment. Case management also includes routine screening in asymptomatic populations at risk for STI-associated adverse outcomes, typically done within clinical services. Another component of STI control is *targeted outreach for high-risk people*,

the core populations contributing disproportionately to disease spread in the community, and who often do not or cannot access facility-based healthcare. Additionally, there is a growing array of *primary prevention interventions* against STI. Last, but as important as the other components, is an *enabling environment* for STI prevention.

STI surveillance

As is true for other public health programmes, accurate STI surveillance is important in understanding the magnitude of the problem, specific STI trends over time, emergence of outbreaks or new problems (e.g. antimicrobial resistance), appropriate deployment of various prevention strategies, prioritization of resources, and monitoring of STI-related public health outcomes. There are several approaches to surveillance that can provide complementary information (WHO 2007a; Douglas and Fenton 2008). First, *case-reporting* provides a measure of new cases of STI or associated syndromes over a specified time interval and is the most common surveillance activity, especially in jurisdictions with functional reporting systems for notifiable infectious diseases. In high-income countries, gonorrhoea, chlamydia, syphilis, and congenital syphilis (i.e. fetal and infant outcomes of MTCT of syphilis) are generally nationally reportable, with reports generated by clinicians, laboratories, or both. In low-income countries where national reporting may be more difficult, reporting from sentinel clinics has proven useful. Second, *prevalence monitoring* can define the prevalence of specific STIs or related syndromes in defined populations undergoing routine assessment (e.g. patients coming for screening or diagnostic testing for infections or for examination for syndromes). Prevalence monitoring can complement case-reporting in assessing the burden of infection or disease. For example, in the United States, while notifiable cases of chlamydia have continually climbed as screening has increased, prevalence monitoring in STI and family planning clinics has shown little change, indicating that the burden of infection is unlikely to be rising (CDC 2010, 2011). Third, *sentinel surveillance* generally refers to data collection from representative 'sentinel populations' for outcomes not routinely measured, such as antimicrobial resistance or infectious aetiology of various STI-related syndromes, and is often useful for generating broader guidance about appropriate treatment regimens and national lists of essential medications. An example of sentinel surveillance is the antenatal HIV and syphilis testing from sentinel clinics done every 1 or 2 years in many countries. Fourth, *population-based surveys* involve collection of data such as prevalence of specific infections from people considered representative of the general population. Population-based surveys are costly and difficult to perform but generally provide the best assessment of population burden. In addition to these approaches for assessing morbidity, periodic surveillance of sexual behaviours, especially those linked to STI prevalence surveys as is done in integrated STI and behavioural surveys conducted in several countries, can provide information about community HIV risk and prevention needs (MacLachlan et al. 2002). Additionally, surveys of health services utilization can be useful in monitoring effectiveness of existing programmes as well as providing information on where prevention services are most needed (Douglas and Fenton 2008). Because of the large burden of disease and limited resources for collection and analysis of STI surveillance data, not to mention sufficient laboratory

capacity, trained personnel and adequate reporting mechanisms, conducting effective STI surveillance can be challenging even in wealthy countries with substantial public health infrastructure. Nonetheless, surveillance is an important STI control component in every country, and especially so in low- and middle-income nations with high STI burden.

Access to STI services

Several clinic-based interventions can improve service accessibility, such as dedicated clinics, broad hours of service delivery, no-charge or low-cost services, and adequately trained and non-judgemental providers. Additionally, broader-level health marketing or social marketing can increase population awareness, attitudes, and beliefs about health services and increase health-seeking behaviour. This has been achieved through various mass media approaches (e.g. printed materials, broadcast media, and the Internet). Numerous examples of social marketing for HIV/STI prevention exist, and although these have not tended to be rigorously evaluated, many social marketing approaches appear to have important community-level effects. For example, a systematic review of the effects of social marketing on condom use in developing countries found positive trends in all studies and an overall positive effect on increasing condom use (Sweat et al. 2012). Some social marketing approaches involve public and private sector partnerships working toward a common public health goal. An example of this is the 'GYT' (Get Yourself Tested) campaign aimed at bringing attention to the growing STD epidemic in youth in the United States (McFarlane et al. in press). That campaign uses a variety of approaches including on-air and online messages, SMS promotions, informational resources, and community outreach.

STI case management

Effective STI case management involves an integrated package of services, including (where laboratory tests are available) routine STI screening in asymptomatic patients at risk for STI-associated sequelae; clinical diagnosis and treatment in symptomatic patients (whether based on laboratory-defined aetiologies or syndromic management); prevention services against new infection or reinfection (e.g. education, individualized prevention counseling, condom demonstrations and provision); and partner management. STI case management—often cited as the backbone of STI control—aims to provide prompt and effective treatment of infected patients and in so doing break the chain of infection. Case management provides individual health benefits (e.g. ameliorating symptoms and preventing complications) and can also provide overall population health benefits. From the perspective of transmission determinants, case management shortens the duration of infection (*D*) and thus reduces efficiency of further transmission in the community. Effective STI case management can be offered in virtually any type of clinical setting, ranging from specialty STI, HIV, and family planning clinics to primary care clinics and antenatal clinic services. However, because of the sensitive and often stigmatizing nature of STIs, particular attention must be paid to offering services that are non-judgemental and confidential, regardless of setting.

Asymptomatic screening and treatment

Routine STI screening is important in identifying asymptomatic infections in populations at risk for adverse outcomes. For

example, many countries recommend annual chlamydia screening in sexually active, young women in order to identify asymptomatic infections that may result in infertility. Universal screening for syphilis and HIV in pregnant women helps prevent MTCT of these infections and subsequent adverse pregnancy outcomes. When STIs are detected, case management strategies including appropriate treatment, prevention services, and partner management should be provided in the same manner as for symptomatic patients, described in the following subsections.

Clinical management of symptoms

In an ideal world, clinical management would be guided by diagnostic tests with results available during the clinical encounter, allowing correct diagnosis and appropriate treatment. Ideal tests would be rapid, affordable, easy to use, and highly sensitive and specific. *Aetiological-based STI diagnosis* using laboratory diagnostics is the approach used in most high-income and many middle-income settings. Although results may not be available right at the clinic visit, in most cases the lab-based testing helps clarify the diagnosis and guides treatment. However, in many parts of the world laboratory capacity is limited and STI tests are generally not available, or are too costly, or results do not return sufficiently quickly and patients are lost to follow up without adequate treatment. Some promising developments have occurred in STI diagnostics in recent years. But given a lack of reliable or affordable diagnostic tests that still exists in many parts of the world, an alternative approach that is used is syndromic case management using locally validated treatment algorithms (Ryan et al. 2008).

STI syndromic case management dates from the 1970s when the WHO designed, implemented and evaluated flowcharts (algorithms) for the syndromic management of STIs, evaluating these in several sub-Saharan African nations (Mabey et al. 2010). Later in the 1990s, locally validated syndromic management approaches were promoted for care of symptomatic STI and other reproductive tract infections (RTIs) (Dallabetta et al. 2007; WHO 2007a; Ryan et al. 2008). STI management was based on the identification of a 'syndrome,' a constellation of easily elicited symptoms and recognizable clinical signs that are associated with a limited number of defined STI or RTI aetiologies. The approach was practical in that it could be carried out in almost any setting (Dallabetta et al. 2007). It did not require laboratory facilities, and patients were treated at the clinical encounter, allowing less chance for complications to develop or for further STI spread to sex partners. Costs were minimized because laboratory tests were avoided and drug regimens were simplified. The use of standardized algorithms covering the most likely conditions reduced treatment failures and the need for repeated visits or referrals to higher level centres. Standardized regimens also helped improve case-reporting for surveillance and, consequently, provide more information for programme management (Dallabetta et al. 2007; Ryan et al. 2008).

STI syndromic management had some important limitations, most critically that it did not address asymptomatic patients, who account for the majority of curable STIs (Dallabetta et al. 2007; WHO 2007a; Ryan et al. 2008). Asymptomatic women with cervical infections are at risk for serious adverse outcomes including tubal damage and infertility, but were poorly covered by this approach. Furthermore, because many genitourinary symptoms

are caused by other conditions in the absence of an STI, the syndromic approach could lead to false positive diagnoses and thus to unnecessary drug use, additional costs and potential partner issues. Partner management was particularly difficult to address as many providers were hesitant to treat sex partners without a specific, laboratory-defined STI diagnosis, even though re-infection of the patient would be very likely without partner treatment. In addition, the most common presenting syndrome for women, vaginal discharge syndrome, is usually caused by non-STI-related RTIs (e.g. bacterial vaginosis, candidiasis) or by other factors. Finally, some healthcare providers, particularly physicians, were reluctant to adopt syndromic approaches because they had been trained in aetiological treatment and viewed the approach as 'unscientific' (Dallabetta et al. 2007; Ryan et al. 2008).

How well syndromic management has controlled STIs in Africa is somewhat difficult to assess. In individual patients, the approach seems most effective for management of genital ulcer syndrome in men and women, urethritis or epididymitis in men, and neonatal conjunctivitis in infants (WHO 2007a; Mabey et al. 2010). Repeated cross-sectional studies in a few nations employing syndromic management approaches suggested that bacterial causes of genital ulcer syndrome markedly declined in parts of Africa, and chancroid (a not uncommon aetiology of genital ulcer disease in the past) seemed to have almost disappeared (WHO 2007a; Paz-Bailey et al. 2005; Makasa et al. 2012). Whether this was due to efficacy of syndromic management or other prevention efforts (e.g. advocacy for 'abstinence, be faithful, use condoms' (ABC) approaches occurring during that time period), or the early deaths of those individuals most likely to develop genital ulcer disease (and thereby HIV) is difficult to ascertain. Perhaps the most compelling evidence of the value of syndromic management was the Mwanza community trial (Grosskurth et al. 1995). However, the study assessed HIV outcomes and did not focus on comparative prevalence of STI syndromes which were considered interim outcomes, and thus any supportive data are limited. Subsequent studies of high-risk men finding higher asymptomatic disease than previously realized have been a further impetus to promote improved syndromic, and ideally aetiological, management strategies (Lewis et al. 2008). Although improved laboratories and availability of point-of-care diagnostics have great potential to support better STI management, unfortunately these are still unavailable in many low- and middle-income countries with high disease burden (Garcia 2011). Thus syndromic management, for all its problems, currently remains a useful management tool as public health practitioners balance potential STI management strategies for the future with the reality of current low budgets and limited public health infrastructure.

Prevention strategies linked to STI case management

Important but sometimes overlooked aspects of STI case management are strategies aimed at preventing reinfection or new infections. Prevention of new STIs has been achieved with informational messages, prevention counselling on risk reduction, educating patients about STIs and how they are transmitted, demonstration of proper condom use and provision of condoms, and ideally a combination of these strategies. Men and women identified with an STI should be educated about the disease and counselled on means of preventing reinfection or new infections. Some individualized prevention approaches are more effective

than others. For example, 'client-centred' counselling in which the provider encourages the patient to set a prevention goal and identify personalized risk reduction steps toward that goal has proven more effective than informational messages (Kamb et al. 1998). Regardless of the prevention approach used, some information should be given about completing therapy, needed follow-up examinations or testing, and preventive strategies (e.g. avoiding risky partnerships, using condoms). Also important is information about notifying sex partners in order to ensure partners are treated and to reduce the chance of reinfection or new infection in the index patient.

Partner management

Breaking the chain of infection involves treating as many sex partners of STI-infected people as possible (Steen et al. 2009). Partner management (referred to in the past as 'contact tracing') actually has many goals: reducing the chance of reinfection in the index patient, treating the partner to avoid future STI sequelae, and limiting community spread of the STI (Hogben et al. 2001; Mathews et al. 2001; Brewer 2005). Although partner management clearly has great potential to be a powerful component of STI case management, it can be difficult to carry out. Two basic approaches have been traditionally applied, *provider referral* (in which health practitioners or public health workers interview the index patient to determine names and locate partners and subsequently notify then confidentially about their exposure and need for treatment and/or testing), and *patient referral* (relying on the index patient to notify partner(s) to come for treatment and/or testing). Where laws allow, another approach that has been successfully employed in parts of the United States is *expedited partner therapy*, in which patients are provided drugs, or prescriptions for drugs, to give to exposed partners (Hogben et al. 2012).

Targeted interventions for core groups

Preventing community spread of STIs depends not on reaching *all* people but reaching the *right* people (Steen et al. 2009). Targeted interventions have a goal of identifying and treating 'core groups'—subpopulations with high STI prevalence and frequent partner change and who thus contribute disproportionately to STI spread in the community. Targeted interventions often involve specialized outreach for subpopulations that are hidden or hard to reach, but can be conducted at 'hot spots' identified through mapping exercises (e.g. bars or nightclubs), in clinical settings (e.g. dedicated clinics for MSM, sex workers, mobile men such as miners), or through peers. Depending upon the local epidemic, targeted efforts may need to address 'bridge populations', that is, those people bridging infection from a higher prevalence subgroup to the general population (e.g. clients of sex workers) (Steen et al. 2009). Effective targeted interventions have included strategies such as 100 per cent condom use campaigns, peer-driven interventions providing information or service referral, periodic presumptive treatment (e.g. for sex workers), STI screening and treatment in HIV-infected people, and supportive laws around clean needles/syringes for injecting drug users (Steen et al. 2009; WHO 2007a, 2012a; UNAIDS 2012). Targeting screening in core groups and bridge populations should not be confused with asymptomatic screening and treatment for STIs in lower-risk populations (e.g. antenatal testing). Targeted screening is aimed at preventing sustained 'upstream' epidemics that contribute to STI

spread in the community while asymptomatic screening in people with low partner change is aimed at preventing STI associated health consequences. Both are important public health interventions, but with different goals.

Primary prevention

For many years primary prevention of STIs relied on ‘ABCs’, that is, abstinence, ‘be faithful’ (i.e. mutual monogamy), and condom use. In fact, substantial evidence supports the effectiveness of the male latex condom in reducing transmission of HIV and other STIs (Weller and Davis 2002; CDC 2010), as well as some serious STI-associated sequelae such as PID and precursor lesions for HPV-associated anogenital cancers (Marazzo and Cates 2011)—although condoms must be used consistently and correctly (Warner et al. 1998). Recent reviews evaluating female condom effectiveness indicate disease prevention benefits similar to male latex condoms (Minnis and Padian 2005; Vijayakuma et al. 2006). Beyond condoms, several exciting developments have occurred in the field of biomedical interventions recently: male circumcision has been proven effective in preventing HIV and other STIs; pre-exposure prophylaxis with antiviral therapy has been found to be highly effective in reducing HIV and HSV acquisition; there are strong supportive data on the benefits of periodic presumptive therapy in preventing disease in sex workers; and perhaps most importantly, there are increasing numbers of efficacious vaccines against STDs (Marazzo and Cates 2011; Gottlieb et al. 2014). Safe and effective vaccines against HPV, HBV, and HAV already exist, although coverage is often inadequate in the countries with highest disease burden. The availability of more affordable vaccines could profoundly affect STI control globally (Vijayakuma et al. 2006).

Enabling environment for STI prevention

Strong programme leadership greatly supports and helps sustain effective STI prevention programmes. Such leadership includes priority setting and planning on STI control efforts, ideally using local data to guide the programme; developing and implementing partnerships that lead to productive collaborations; and ensuring ongoing programme quality. However, regardless of how effectively a programme prioritizes, collaborates and implements STI prevention programmes, it will have difficulty producing sustainable benefits without an enabling environment, that is, the political will and resources to support prevention and control efforts. An enabling environment encompasses a number of factors such as a supportive legal and regulatory milieu, the ability to secure sufficient financial and human resources for the programme and for basic science and public health evaluation research, and the ability to effectively advocate for programme priorities within the community and at the highest levels.

Some examples of laws or policies that can positively affect STI prevention programmes are the ability to provide confidential clinical services to minors without parental consent, the ability of health practitioners (e.g. nurses) responsible for STI case management to provide services and prescribe drugs, and the permissibility of expedited partner therapy (Mathews et al. 2001; Brewer 2005; WHO 2007a; CDC 2010). Securing financial resources for STI prevention is critical at many levels; examples are to ensure: sufficient programme dollars to sufficiently cover STI clinical services; availability of free (or affordable) treatment for

STI-infected people; availability of prevention services; funding for ongoing monitoring and evaluation and training; and needed human resources. Such resources include an adequate workforce trained in appropriate STI clinical management, partner management, prevention services, surveillance, outreach, and evaluation. Developing an adequate public health workforce is difficult in many countries, but especially so in sub-Saharan Africa where there are grave shortages in healthcare workers in all sectors due to limited resources for educating professionals. This has been compounded by ‘brain drain’, when trained professionals leave to go to wealthier countries experiencing shortages or to donor agencies able to pay higher prices than governments.

Programmes are most effective when decision-makers can promote supportive laws and policies, raise political awareness about problems, and help mobilize resources around STI prevention and control. Political support from the top is especially important for conditions such as STIs because their associated stigma can make public discussion and community involvement difficult. But when political support exists, the results can be profound. For example, in the 1990s, Thailand had a 95 per cent reduction in curable STIs following introduction of its 100 per cent condom use programme for sex workers, and Cambodia also had STI decreases after introducing a similar campaign; both were strongly supported by the governments (Steen et al. 2009). In Senegal, where sex work has been decriminalized and STI services made accessible to sex workers, STI prevalence has remained moderately low and stable, in contrast to neighbouring countries without such laws (Steen et al. 2009). In Switzerland, low HIV and hepatitis prevalence among drug users has been attributed to pragmatic policies supporting harm reduction strategies (Csete et al. 2012). The Public Health Agency of Canada’s development of sexual health indicators (i.e. physical mental, emotional, and social well-being in relation to sexuality; approach to sexuality; sexual relationships; sexual experiences; and discrimination, coercion, and violence) allows measurement of trends in several dimensions of sexual health, thereby helping public health leaders to target interventions appropriately for young people (Smylie et al. 2013).

Future directions and challenges

Antimicrobial resistance has been an important factor in STI control since the development of antibiotics in the early part of the twentieth century. The recent emergence of highly resistant gonorrhoea strains in the face of a single remaining antibiotic class will prove to be an important challenge in the next decades. On the other hand, supportive global initiatives, new and improved STI diagnostics, and better information and communication technologies are already supporting improved STD control and will continue to do so in the future.

Global and regional initiatives

In May 2006, the WHO announced a new *Global Strategy for the Prevention and Control of Sexually Transmitted Infections: 2006–2015: Breaking the Chain of Transmission*, which was developed using an inclusive and broad consultative process and presented and accepted at the World Assembly (WHO 2007a). The strategy emphasized the importance of scaling up STI prevention activities, better integration of STI prevention with other public health programmes, and a focus on technical advances and

advocacy. The strategy also highlighted ten actionable interventions for immediate implementation, and provided indicators and national-level targets for each: (1) scaling up services for diagnosis and treatment of STIs; (2) control of congenital syphilis as a step towards elimination; (3) scale-up of STI prevention strategies and programmes for HIV-positive people; (4) upgrading surveillance of STIs within the context of second-generation HIV surveillance; (5) control of bacterial genital ulcer disease; (6) implementation of targeted interventions in high-risk and vulnerable populations; (7) implementation of age-appropriate, comprehensive sexual health education and services; (8) promoting partner treatment and prevention of reinfection; (9) supporting roll-out of effective vaccines against HBV and HPV and, potentially, HSV-2; and (10) facilitating development and implementation of universal opt-out voluntary counselling and testing for HIV among patients with STIs. Many countries have reported progress in these areas; and perhaps the greatest measurable global progress has been in prevention of congenital syphilis.

In 2007, the WHO published *The Global Elimination of Congenital Syphilis: Rationale and Strategy for Action* outlining the estimated burden of disease, including the substantial contribution of MTCT of syphilis to infant mortality and morbidity (WHO 2007b). Subsequently the WHO, working with global partners including the US CDC, formally launched a global elimination campaign. The global congenital syphilis elimination initiative uses a four-pronged strategy of ensuring advocacy and sustained political commitment for a successful health initiative; increasing access to and quality of maternal and newborn health services; screening and treating pregnant women and partners; and establishing surveillance, monitoring and evaluation systems. The global initiative has had strong support from regions, as well as many high-burden countries (WHO 2007c). Several regional initiatives supporting congenital syphilis elimination were launched: in 2009, the Pan American Health Organization and UNICEF began the *Regional Initiative for the Elimination of Mother-to-Child Transmission of HIV and Syphilis in Latin America and the Caribbean* (Pan American Health Organization 2009), coupling two critical antenatal screening programmes and thus promoting a synergistic and, hopefully, more sustained and supportive programmatic response. In 2010, an Asia Pacific United Nations Task Force representing the regions of the Western Pacific and South East Asia adopted a similar dual elimination initiative aimed at elimination of new paediatric HIV infections and congenital syphilis in Asia-Pacific, 2011–2015 (WHO 2011). Several countries of sub-Saharan Africa developed plans for dual elimination of MTCT of HIV and syphilis.

The results of these efforts have been enhanced congenital syphilis surveillance, adoption of regional case definitions and management guidelines, and greatly improved programme monitoring of uptake of antenatal syphilis testing and appropriate treatment. The increasing use of rapid syphilis tests in antenatal clinics has further contributed to increased testing in many settings with limited laboratory capacity (Mabey et al. 2012). Rapid testing has also promoted higher treatment uptake, as treatment can be provided at the clinic visit. The WHO, working through regional offices, has encouraged countries to actively measure programme progress and work toward elimination of congenital syphilis, an important cause of preventable perinatal morbidity and mortality. Recent global estimates suggest decreases in MTCT of syphilis

have occurred since 2000 (Newman et al. 2013). In addition, at least one region (the Americas) is developing methodologies to validate elimination in countries where leaders believe elimination goals have been met. Despite these developments, progress is slow in many areas, particularly in sub-Saharan Africa where burden is high. Although integrating syphilis and HIV testing for antenatal women has been found to be a sound and cost-effective strategy (WHO 2007c; Mabey et al. 2012; Strasser et al. 2012), it has been slow to be taken up in many countries—in large part due to disease-specific funding.

Antimicrobial resistance

The rapidly evolving resistance of *Neisseria gonorrhoeae*, among the world's most common curable STIs, to successive antimicrobial agents has been concerning for several decades. However, the relatively recent emergence of highly resistant strains that are increasingly less susceptible to third-generation cephalosporins—the single remaining class of antibiotics active against the pathogen—has led to some alarm around the world (Bolan et al. 2012).

N. gonorrhoeae is a highly active organism that has readily developed resistance to antimicrobial agents. Resistance to sulphanilamide was identified as early as the 1940s. Penicillinase-producing strains were isolated as early as the 1970s in South East Asia and subsequently spread widely throughout the world (Bolan et al. 2012). Resistance to other first-line therapies such as spectinomycin and tetracycline emerged in Asia in the 1980s. Fluoroquinolone-resistant gonorrhoea strains were observed in several Asian countries in the 1990s, and high levels of fluoroquinolone resistance subsequently spread throughout Asia and other parts of the world by the early 2000s (WHO 2000). With loss of the quinolone class, at present the third-generation cephalosporins are the single line of defence against gonorrhoea; and sporadic reports of resistance to cefixime are already reported (Ohnishi et al. 2011). Furthermore, increases in minimum inhibitory concentrations (MIC) of third-generation cephalosporins are now observed in laboratories around the world. Many nations have adopted steps to try to delay the emergence of cephalosporin-resistant gonorrhoea strains and reduce the public health consequences, primarily through educating clinicians and updating treatment recommendations to higher doses of intramuscular ceftriaxone, often including single-dose azithromycin or doxycycline (CDC 2013). New drugs effective against gonorrhoea are obviously important, but new drug development takes time and the organism has been highly successful in quickly developing resistance. As was the case for tuberculosis, treatment for gonorrhoea is anticipated to eventually require multiple antibiotics for cure. An effective vaccine would obviously be an ideal solution, although none is on the immediate horizon.

The WHO has initiated a *Gonococcal Antimicrobial Surveillance Programme* (GASP) to help monitor gonorrhoea resistance worldwide through a network of laboratories, WHO collaborating centres, and other international and national reference centres. Participating laboratories from each region have agreed to submit gonococcal antimicrobial susceptibility data to the regional WHO collaborating centre, where data are analysed, summarized and can be disseminated globally. Unfortunately, *N. gonorrhoeae* is a fastidious organism that has proven difficult to transport and successfully culture. Because of this, gonococcal culture and antimicrobial susceptibility testing is lacking in countries with

limited laboratory capacity or trained personnel. However, even in wealthy countries, the capacity for culture (and thereby antimicrobial susceptibility testing) has been increasingly lost with the wider use of simpler molecular technologies such as NAATs. Currently most surveillance data on gonorrhoea antimicrobial resistance are available from laboratories from the Western and South East Asian Regions, Europe, and North America, although the WHO has prioritized expansion of GASP as part of their future agenda.

Antimicrobial resistance is also emerging for *Haemophilus ducreyi*, the causative agent of chancroid, although oral antibiotic therapies are still effective against this increasingly rare disease (Ryan et al. 2008). Azithromycin resistance in syphilis has been reported in a few settings, although the geographic distribution of resistant strains has not been well established, and *T. pallidum* remains exquisitely sensitive to penicillin, the first-line recommended therapy (Lukehart et al. 2004). Resistance of *T. vaginalis* to standard treatment with single-dose metronidazole occurs occasionally, requiring lengthier drug regimens or alternative treatments (Fortenberry et al. 2002). Additionally, while resistance of HSV-2 to aciclovir and related antiviral regimens is uncommon in immune-competent patients, it has been observed to occur in from 3.5 to 10 per cent of immune-compromised (e.g. HIV-infected) patients (Piret and Boivin 2011).

Information and communication technologies

Information and communication technologies (ICTs) are evolving rapidly, and nowadays the Internet, mobile devices, and cell phones and other gadgets could enable lower cost and highly engaging STI prevention and control interventions (Swendeman and Rotheram-Borus 2010). ICTs could help in diagnosing medical conditions, screening, recognizing behaviours, delivering 'just-in-time' interventions and improving surveillance systems. The Internet constitutes a potential source of information in health where patients can search for symptoms, diagnosis, or treatment, and seek out healthcare providers (Rietmeijer et al. 2003). However, the Internet has also facilitated social interactions and networking, making it easy to seek for sexual partners, and thus increasing the risk for acquiring STIs. It has been recognized that MSM are the group that more actively engaged in these practices (Ogilvie et al. 2008). Nevertheless, the Internet has proven to be an effective and low-cost tool to deliver STI prevention interventions, including partner notifications (CDC 2003; Bull et al. 2004; Levine et al. 2005; Bowen et al. 2007). Computer-based and Internet-based behavioural interventions against STIs have demonstrated efficacy comparable to face-to-face interventions (Swendeman and Rotheram-Borus 2010).

Mobile health or 'mHealth' refers to the use of mobile devices for health applications aimed at improving individuals' health and well-being through monitoring their status, improving diagnosis of medical conditions, recognizing risk behaviours, and delivering interventions—all in the user's natural mobile environment. The most common mobile devices are cellular phones; these have had incredible penetration in the population, with subscriptions globally surpassing the 5 billion mark, two-thirds of which are in low- and middle-income countries. Mobile phones have the capacity to be used to send information to patients, send reminders for appointments or medications, gather information or, with additional attachments, monitor vital signs, or even read

and transmit diagnostic test results. Most of these applications are still under development; however, several ongoing mHealth pilot studies are assessing various uses of the technology. Mobile phone interventions against STIs using text-messaging or SMS are being used in several areas. Thus far, mHealth applications have been found effective in increasing adherence to antiretroviral therapies in HIV-infected patients. There is a need for high-quality research in this area aimed at STI prevention and care (Free et al. 2013).

New STI diagnostics

Great progress has been made over the past two decades in the development of rapid (i.e. point-of-care) diagnostic tests that facilitate screening and treatment of STIs, especially in settings in which it is currently difficult to provide testing (e.g. limited laboratory capacity) or in which it is difficult for patients to learn results and receive prompt treatment if results are positive (e.g. remote, hard-to-reach settings). Rapid tests are particularly useful for asymptomatic patients, but can also be useful for symptomatic patients when more sensitive and specific diagnostic tests are unaffordable. Many high-quality rapid tests exist for HIV. The use of rapid diagnostics also has the potential to improve syndromic management of STIs by increasing the specificity of the algorithms and thus reducing unnecessary treatment (e.g. for women with vaginitis).

Promotion for the development, application, and evaluation of rapid STI diagnostics appropriate for use in primary healthcare in developing countries was greatly advanced by the work of the Sexually Transmitted Diseases Diagnostics Initiative (SDI), a unit of the UNICEF/UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases (Peeling et al. 2006). The SDI focused on tests that met the 'ASSURED' criteria, that is, were *affordable*, *sensitive*, *specific*, *user-friendly* (simple enough to perform in a few steps and with minimal training), *rapid* and *robust* (to enable treatment at the first visit, and not requiring refrigeration), *equipment-free* (easy and with a non-invasive way to collect specimens), and *delivered* to end users (Peeling et al. 2006). Development of rapid tests for syphilis has been particularly productive. Many rapid treponemal tests for syphilis exist, and at least six of these were formally evaluated by the SDI and found to meet ASSURED criteria. Although a positive treponemal test indicates lifetime exposure to syphilis, and cannot distinguish new and old infections without non-treponemal testing, treponemal tests alone can be very useful among pregnant women who would otherwise not be tested for syphilis. This is because risk for overtreatment (penicillin injection) is low compared with the risk of untreated syphilis for the infant (> 50 per cent fetal morbidity or mortality) (Mabey et al. 2012). Treponemal tests (by themselves) would be less useful in populations, such as sex workers or MSM, likely to have been treated for past syphilis infection. A rapid treponemal/non-treponemal test on a single platform has been developed, allowing screening and confirmation of syphilis. Additionally, several combined HIV and syphilis tests on a single platform have been developed and are under evaluation.

Development of sensitive and specific rapid tests for gonorrhoea or chlamydia has been less successful. However, a closed-system NAAT assay has been developed that involves a modular-cartridge-based platform that is easy to use, minimizes processing steps and contamination, and can process from one to 96 specimens in less than 2 hours. A formal evaluation of these

chlamydia and gonorrhoea tests indicated solid performance when compared against laboratory-based PCR tests (Gaydos et al. 2013). Thus, although not useful in developing world settings lacking basic infrastructure, this type of user-friendly system with short turnaround times could be extremely useful in many clinical settings to accurately test patients for chlamydia and gonorrhoea at the point of care, allowing treatment to be promptly initiated.

Conclusions

At the beginning of the twenty-first century, STIs continue to be a major global health problem, accounting for substantial reproductive, perinatal, and cancer-related morbidity and mortality in addition to contributing to HIV transmission. This chapter has outlined key issues around STI transmission, prevention, and effective STI programmes. Newer strategies such as rapid point-of-care and other diagnostics with short turn-around times; simple and easy-to-use information and communication technologies; improved vaccines and therapeutics; and supportive global and regional initiatives are all anticipated to help control STIs all over the world. However, many challenges remain. In an era of increasingly available and affordable interventions and widespread HIV treatment and prevention programmes, some very basic STI control strategies (e.g. routine syphilis screening of pregnant women; gonorrhoea culture and sensitivity testing) are not yet well implemented, especially in low-income settings. New problems are also emerging in STIs, particularly the emergence of increasing gonococcal antimicrobial resistance to the final class of drugs effective against that organism. Widespread vaccine uptake against STIs has been slow. After 30 years, HBV vaccine is finally increasingly accepted; however, coverage of the recently available HPV vaccines remains spotty even in wealthy nations, and its use is low or non-existent in most middle- and low-income countries. Although there are no new vaccines against viral STIs on the immediate horizon, research in this area must continue. In the meantime, strategies that increase coverage of existing vaccines remain a priority.

STIs are stigmatizing conditions that have their greatest effects on vulnerable or marginalized populations, and thus mobilizing societal and political support for their prevention and control remains an important challenge for all nations. Given the high individual and societal costs associated with STIs, and the great potential to prevent them, efforts to sustain and scale up effective STI control programmes must remain an important global health priority.

Sten H. Vermund and Suniti Solomon

Current status of the HIV/AIDS epidemic

The global pandemic of human immunodeficiency virus (HIV) infection is unprecedented in human history. While the bubonic plague in fourteenth-century Europe is estimated to have killed a quarter of the population, the epidemic of 1347–1350 was self-limited once a vast pool of susceptible humans and rodents were killed and people who recovered were immune (McEvedy 1988). Plague re-emerged periodically, but infrequently and with less intensity than the original devastating disease, and was not reported in Europe in epidemic form after the eighteenth century. In contrast, HIV emerged as a global pandemic in the 1980s and is now endemic throughout the world, declining only slightly in the first decade of the twenty-first century (Kilmarx 2009; Vermund and Leigh-Brown 2012). HIV is primarily a sexually transmitted infection (STI) and is propagated by human behaviour. Without successful control by biological and behavioural means, HIV will not be so readily controlled as was *Yersinia pestis*, the plague bacterium that was controllable with improved sanitation and rodent control well before the era of antibiotics.

An analogous global pandemic threat is that of influenza; its challenges in viral mutation and recombination and the risk of poor vaccine availability and coverage are, perhaps, as alarming as HIV as a risk to the global populace (Fedson 2009). That HIV disease, unknown until 1981, should have joined respiratory and diarrhoeal diseases, tuberculosis, malaria, and vaccine-preventable diseases like measles as the most devastating of global infectious threats reminds us of the need for vigilance in recognition and response to emerging infectious diseases (Chavers and Vermund 2007).

In countries most affected in southern Africa, HIV prevalence rates in the general adult population routinely exceed one in ten adults and rise to as high as one in two in certain age/sex groups (Karim et al. 2011). The self-perpetuating transmission cycles are facilitated by human sexual behaviours as well as the decade-long average incubation period of the virus. Rather than infecting and killing many people quickly, like plague or influenza, HIV is transmitted more gradually and kills people well after they may have infected others (Baggaley and Fraser 2010).

Advanced clinical or immunological disease has been termed the acquired immune deficiency syndrome (AIDS), a concept still useful for surveillance but imprecise for use in clinical medicine; there are many more gradations and variations of HIV disease than the binary 'AIDS' or 'no AIDS' designations. People with

AIDS-defining opportunistic infections (OI) or malignancies (OM) in the pre-treatment era (before 1987) were typically severely immunologically suppressed; people with CD4+ T-lymphocyte counts under 200 cells/microlitre were ultimately included in the AIDS case definition as revised by the US Centers for Disease Control and Prevention (CDC) in 1993 (Anonymous 1992). But in the combination antiretroviral therapy (cART) era after 1996, people with AIDS could achieve levels of immunological reconstitution sufficient to permit decades of disease-free life. Hence in the era of cART, reaching a surveillance case definition of AIDS no longer suggests that an individual has current severe HIV disease, they may have partial immune reconstitution if they have received cART. This chapter will refer to HIV disease in all its levels of severity, referring to AIDS only when discussing surveillance data that use AIDS as a surrogate for advanced HIV disease.¹

Global HIV trends

As of the end of 2011, an estimated 34 million people globally were living with HIV infection, 95–97 per cent of whom were in low- and middle-income countries (LMIC) (Joint United Nations Programme on HIV/AIDS (UNAIDS) 2011a). In 2012, UNAIDS and the World Health Organization (WHO) estimated that the pandemic would pass the 30 million cumulative HIV mortality mark; in dozens of nations, HIV is the first ranking cause of death for young adults aged 20–44 years (UNAIDS 2011b). While continuing to expand in some nations (like Pakistan) and in some subpopulations (like black men who have sex with men (MSM) in the United States), the prevalence has peaked and declined by varying degrees in a number of afflicted nations and/or population subgroups. In Thailand and Uganda, the success of control efforts predated the advent of cART and was attributed to behavioural and structural changes (Stoneburner and Low-Beer 2004; Kipp et al. 2009; Park et al. 2010). In southern sub-Saharan Africa where HIV rates are the highest, there is evidence of declining prevalence and incidence, as has been well documented in Zimbabwe (Halperin et al. 2011). Deaths may have contributed to declining prevalence (Wawer et al. 1997), though in the face of expanded cART availability, declining prevalence and incidence may well be related (Das et al. 2010).

In some parts of the world, incidence is stable and even rising, especially in selected vulnerable subgroups such as MSM in Asia, black MSM in the United States, or people who inject drugs (PWID) in Eastern Europe and central Asia (Kilmarx

2009; El-Sadr et al. 2010; Vermund et al. 2010; Beyrer et al. 2011). Successes are reported, but given that rates remain high in the general population in sub-Saharan Africa, and are persistent in most at-risk populations throughout the world, no serious observer predicts the spontaneous demise of the pandemic (Vergara et al. 2009; Larson et al. 2011; Schwartlander et al. 2011).

Children are affected in many ways by the epidemic. They may be infected through mother-to-child transmission (MTCT) *in utero*, during delivery, or post-partum via breast milk (Goldenberg et al. 2002; Fowler et al. 2010; Mofenson 2010). HIV-exposed, but uninfected infants can suffer due to the loss of one or more parents due to HIV, or due to their illness itself with its economic and social burden on the family (Newell et al. 2004). Adolescents (or abused children) can be infected sexually and may be challenging to engage in successful and sustained primary care (Ding et al. 2009). Prevention of MTCT is challenged by programmatic obstacles that are amenable to quality improvement research and intervention (Stringer et al. 2003, 2005; Bolton-Moore et al. 2007; Reithinger et al. 2007; Potter et al. 2008; Megazzini et al. 2010; Stringer et al. 2010). Prevention programmes are judged to be highly cost-effective and are the focus for intensive pregnancy screening and ART intervention (Galarraga et al. 2011). Early infant diagnosis leading to earlier cART therapy is essential to improve outcomes for HIV-infected infants (Violari et al. 2008; Ciampa et al. 2011; Ciaranello et al. 2011).

An alarming trend is one familiar to the field of STIs, namely the replenishing of the at-risk population with sexually vulnerable youth; about half of the global population is under age 25 and this corresponds to the proportion of new infections globally attributable to this age group (UNAIDS 2011b). However, since the average age of sexual debut is in the teens, this suggests the intensity of risk for adolescents and youth once they become sexually active (Underhill et al. 2007; DiClemente et al. 2008; Spiegel and Futterman 2009; Karim et al. 2011).

HIV morbidity and mortality has had a huge impact on economies of LMIC (Ferreira et al. 2011). Given the link of HIV with vulnerable populations and/or poverty, such challenges as community development, orphans, household income, and gender-power issues have been exacerbated by the HIV pandemic (Andrews et al. 2006; Hosegood et al. 2007). Disease progression and transmission of other infectious diseases, notably tuberculosis, are accelerated by HIV co-infection (Lawn and Zumla 2011; Martinson et al. 2011). Cancers such as Kaposi's sarcoma (human herpesvirus type 8 (HHV-8) co-infection) and cervical cancer (human papillomavirus (HPV) co-infection) loom large as major risks (Casper 2011; Sahasrabudde et al. 2012). In addition, the progression of HIV and its infectiousness is exacerbated by other co-infections (Modjarrad and Vermund 2010; Barnabas et al. 2011). Food insecurity may limit cART adherence when appetites surge with immune reconstitution and increased energy and metabolic demands (Koethe and Heimbürger 2010). Hence, the global community is increasingly embracing a more holistic response to the HIV pandemic, including community development, task shifting for healthcare workers, and horizontal health system reform, while acknowledging the need for sustained emergency responses (Chopra et al. 2009). HIV may be among the most important healthcare challenges in endemic nations, but it is hardly the only one.

HIV by continent/region

Sub-Saharan Africa

Over a third of the infected people globally live in ten nations of southern Africa, by far the worst afflicted region. South Africa, for example, was the 25th most populous nation with 49 million people in mid-2009 (United States Census Bureau n.d.). Yet it ranked first for the number of people living with HIV/AIDS with an estimated 5.6 million people (range 5.4–5.9 million) in 2009 (UNAIDS n.d.). South African adults aged 15 to 49 years had an estimated 2009 prevalence rate of 17.8 per cent (range 17.2–18.3 per cent); nearly 2 million children had been orphaned by 2009. Averages mask extremes; some subpopulations in their mid 20s were over 50 per cent HIV-infected (Karim et al. 2011).

The sub-Saharan African epidemic is driven by heterosexual contact (Vermund et al. 2009). Injection drug use and male-to-male sexual contact may be increasing and represent future risk (Vlahov et al. 2010). Iatrogenic spread has also been reported through reuse of contaminated needles and use of contaminated blood products in healthcare settings (Simonsen et al. 1999; Beyrer et al. 2011). However, the overwhelming burden of transmission is, and remains of, heterosexual origin. MTCT is still common in sub-Saharan Africa due to failures to achieve high coverage of HIV testing in pregnancy and proper mother–infant coverage with ART (Stringer et al. 2003, 2005, 2010; Horwood et al. 2010). Given its large population and its low coverage rates for prevention of MTCT, Nigeria has more unmet need for HIV screening of pregnant women than any other African country.

East and South East Asia

The epidemic in South East Asia, China, Japan, Philippines, Indonesia, and other parts of the region is a complex one. While less intense than in Africa, the Asian epidemic remains intractable with persistent transmission in vulnerable populations. Countries like Japan, Korea, and Mongolia report a disproportionate number of imported HIV cases, with low indigenous transmission rates; however, high-risk populations such as MSM in Japan and STI patients in Mongolia suggest concern for future autochthonous transmission (Nemoto 2004; Davaalkham et al. 2009). In the Philippines, vulnerable populations have had surprisingly low rates of infection, but some observers believe that over time, local HIV transmission will increase (Farr and Wilson 2010). In South East Asia and Indonesia, heterosexual, MSM, and PWID transmission are all prevalent (Sharma et al. 2009; van Griensven and de Lind van Wijngaarden 2010; Vlahov et al. 2010; Couture et al. 2011). In countries like Thailand and Cambodia, successes are notable in reducing transmission among PWID and heterosexual transmission with needle exchange and universal condom advocacy, respectively (Celentano et al. 1998; Park et al. 2010). China has had some progress in addressing its serious problem of HIV among PWID, but the epidemic among MSM is rising; fortunately, heterosexual spread is not common in the world's most populous nation, even among sex workers (Wu et al. 2007; Xiao et al. 2007). An unusual outbreak of HIV in rural central China spread due to pooled red cell re-infusions to blood and plasma donors who were illegally and unethically recruited in the 1990s (Qian et al. 2005, 2006).

South Asia

India has experienced a substantial heterosexual epidemic concentrated in its southern states, with PWID-related transmission

in northeastern states; the northern states have much lower incidence and prevalence (Chandrasekaran et al. 2006). Despite prevalence rates far lower than in sub-Saharan Africa, India, the second most populous nation on the globe, ranks just behind South Africa and Nigeria for the highest number of HIV-infected people (about 2.5 million in 2009) living in the nation. MSM are at risk throughout south Asia, including *hijras*, who are men who dress as women and have a long-standing cultural niche in such nations as India, Pakistan, and Bangladesh (Solomon et al. 2010; Siddiqui et al. 2011; Sahastrabudde et al. 2012). India faces Asia's largest unmet need for prevention of MTCT, with daunting challenges to screen vast populations of pregnant women. India's HIV rates are far higher in the south and the northeast of the nation than in the north-central or northwest. An explosive growth in HIV prevalence seen in Pakistan in 2002 underscores the fact that where risk behaviour persists, HIV is likely to spread eventually (Altaf et al. 2009; Kazi et al. 2010).

Eastern Europe and Central Asia

Although same-sex and heterosexual transmissions occur in Eastern Europe and Central Asia, most HIV transmission has been from PWID (Mathers et al. 2010). A number of countries continue to have growth in their epidemics, even as prevalence rates stabilize or even decline elsewhere in the world (Kelly and Amirkhanian 2003). While rates in Eastern Europe and Central Asia have not reached the levels elsewhere, exceedingly poor policies that have undermined risk reduction efforts among PWID have exacerbated the epidemic, most notably in Russia, a country that continues to ban any form of opiate substitution therapy (i.e. methadone or buprenorphine) (Elovich and Drucker 2008; Bridge et al. 2010). Where aggressive risk reduction has been promulgated using clean needle and syringe exchange, results have been very promising (Platt et al. 2008). All of this is sadly reminiscent of the policy blind spots in the United States that banned federal support of clean needle exchange until Congress lifted the ban in 2009; current US policies and plans are based more on prevention evidence rather than the political concerns of the past (Lurie and Drucker 1997).

Middle East and North Africa

Sexual transmission of HIV is reported in the Middle East and North Africa, particularly among MSM (Mumtaz et al. 2010). Migrant workers in the Gulf States are deported if infected, and can serve to introduce HIV in their home countries (Shah et al. 1999). Commercial sex workers have not had high rates, perhaps due to cultural and biological factors of near-universal male circumcision and lower partner exchange rates in the general population (Abu-Raddad et al. 2010). It is also true that if a foreign sex worker tests HIV-positive, she/he is deported, reducing HIV prevalence in the middle eastern nation doing the deporting. PWID has been the largest driver of transmission in this low-prevalence region (Todd et al. 2007; Sawires et al. 2009). Given its suppressive human rights policies, it is a paradox that Iran has been at the regional forefront of an assertive response to use of opiate substitution therapy to reduce drug craving and HIV risk, including services in prisons (Farnia et al. 2010).

North America and Western Europe

The HIV epidemic in North America and Western Europe has been driven by MSM, PWID, and, to a lesser extent, heterosexual

transmission (Vermund and Leigh-Brown 2012). Sexual vulnerability is higher in people practising unprotected anal intercourse and using alcohol and/or illicit drugs proximate to sexual activity (Miller 2003; Shoptaw and Reback 2007). Party drugs (e.g. nitrates, amphetamines, and cocaine) have been associated with higher-risk sexual activity, an observation dating from before we even knew that HIV caused AIDS (Goedert 1984). People addicted to crack cocaine and methamphetamine may practise high-risk sex and both women and men may sell sex for drugs or money to support drug habits (Corsi and Booth 2008). Adolescents are vulnerable to peer pressures to have sex and use drugs (Fortenberry 1998). Affected subgroups have changed over time in the United States, for example, increasing numbers of MSM of black and other minority ethnic backgrounds and women, together over half the incident cases (Millett et al. 2006; El-Sadr et al. 2010). Molecular phylogenetic approaches have established historical links between HIV strains from central Africa to those in the United States and thence to Europe (Vermund and Leigh-Brown 2012). As in other high-income nations, HIV screening has virtually eliminated blood/blood product-related transmissions. MTCT has been reduced markedly since the 1980s, with peripartum ART prophylaxis in HIV-infected pregnant women and exposed newborns combined with discouragement of breastfeeding among HIV-infected mothers; MTCT of HIV is a rare public health problem in high-income nations, though some perinatal cases are still seen (Lindegren et al. 1999).

Given the value of HIV therapy in reducing infectiousness, as demonstrated by the HIV Prevention Trials Network 052 protocol (HPTN 052, discussed later in this chapter), it is disappointing that only 19–28 per cent (range of estimates from 2010) of Americans infected with HIV were on cART with successful suppression of HIV viral load (Burns et al. 2010; CDC 2011; Cohen et al. 2011; Gardner et al. 2011). High-access cities like Vancouver and San Francisco do much better and may be seeing prevention benefits from high HIV testing and cART coverage (Das et al. 2010; Montaner et al. 2010). Aggressive testing and cART use within the context of excellent primary care may also contribute to lower-than-expected HIV rates in Western European countries, though other cultural elements and aggressive prevention interventions make this hard to disentangle. Declining incidence due to wider coverage with cART has been suggested in other high-income nations as well, for example, Taiwan (Fang et al. 2004).

Central and South America

There is diversity in the south and central American epidemic, but the dominant mode of transmission seems to be anal sex among MSM (Bastos et al. 2008). PWID contributes substantially in some regions such as urban Brazil, but is a less common risk factor than in North America, Europe, or Asia (Hacker et al. 2005). Alcohol and non-injection use fuel unsafe sexual behaviours (Bastos et al. 2007; Bassols et al. 2010). Heterosexual transmission occurs and bisexual men are thought to be an important bridge population (Ramirez et al. 1994; Konda et al. 2011). Perinatal transmission is less common with most antenatal programmes in endemic areas offering HIV testing and ART, albeit imperfectly (D'Ippolito et al. 2007).

Caribbean

The second highest prevalence rates in the world, after sub-Saharan Africa, occur in the Caribbean region (Figuerola

2008). The epidemic is diverse with the worst affected nation, Haiti, experiencing a heterosexual-dominant pattern (Castro and Farmer 2005; Dorjgochoo et al. 2009). The Dominican Republic and Guyana also have substantial heterosexual transmission (Allen et al. 2006; Padilla et al. 2008; Seguy et al. 2008). MSM represent the more common afflicted group in most of the other islands (Finlinson et al. 2006; Padilla et al. 2008). Puerto Rico is a territory of the United States with close ties to major US cities like New York and Miami (connected by so-called ‘air bridges’ of low-cost, passport-free travel); Puerto Rico has been experiencing an substantial PWID-related transmission (Mino et al. 2011). Cuba is well-known for its mass HIV screening and quarantine approach to HIV, segregating HIV-infected people into their own communities; this has alternatively been criticized for human rights restrictions and been praised for limiting the epidemic’s spread (Anderson 2009; Hsieh et al. 2010). Adolescents, as in the rest of the world, are of special concern for sexual risk behaviours (Dorjgochoo et al. 2009; Andrews 2011).

Selected mainland countries like Guyana (in South America) and Belize (in Central America) are often grouped with Caribbean countries due to proximity and socio-political synergies, even though they are not islands. Both Guyana and Belize are in the Caribbean Community and Common Market (CARICOM) and have formal public health ties with the English-speaking islands through the Caribbean Epidemiology Centre (CAREC) in Trinidad. Guyana was chosen, along with Haiti, as one of the first target countries for large US investments for HIV control and prevention, the President’s Emergency Plan For AIDS Relief (PEPFAR).

Australia and Oceania

Australia has had a persistent and aggressive risk reduction programme from the early days of their epidemic (Jones et al. 2010; Kang et al. 2010; Mao et al. 2011). Their widespread and ‘user-friendly’ approaches to clean needle exchange and availability of opiate substitutions therapy through primary care practitioners are credited for keeping HIV rates exceedingly low in PWID (Miller et al. 2009). MSM is a principal challenge in parts of the region, though Oceania confronts pockets of heterosexual transmission (Corner et al. 2005; Valley et al. 2010).

In summary, each global region has its specific challenges to confront in HIV control. Even at the micro-geographic level, there can be differences of just miles or even city blocks where PWID drives a micro-transmission dynamic versus sexual activity driving a local epidemic. Infection control efforts must be based in an epidemiological knowledge of the transmission drivers and sociocultural contexts of risk behaviours in a given region, or even a given neighbourhood. ‘Know your epidemic’ has become the adage that reminds us that a given prevention approach will not work in all settings. At the same time, there are great truths in the global pandemic: behaviour change is a vital component of any part of the effort to control transmission; high cART coverage may reduce community-level transmission; risk reduction strategies can work to reduce HIV transmissions even if the underlying challenges (e.g. PWID, sex work) are not altered markedly; risk behaviours are steeped in cultural context and traditions that are not easily changed; human rights underlie the global community’s response, successful or unsuccessful, as respect for vulnerable people is the first step towards engagement and assistance.

Regional and national data are updated yearly by UNAIDS (2014) and WHO (2014).

Biological mechanisms

Unique HIV characteristics

It is unhelpful to consider HIV merely as an infectious disease; it needs also to be considered a chronic disease. Only with this merger of the infectious disease–chronic disease ‘dichotomy’ can one understand the challenges ahead for HIV control. The life-span of the infected individual can vary from years to decades; this is not a classic infection paradigm of infection followed by either immunological control/recovery or death, as applies to so many other viruses. Examples of the classic infectious disease paradigm are vaccine-preventable diseases of childhood like measles and arboviruses like yellow fever; they may kill, but in people who survive, they provide lifelong immunity.

In contrast, HIV persists even in the face of the host’s immunological response. Lentiviruses (i.e. slow viruses) are characterized by years and even decades of gradual pathogenic impact. The HIV-infected individual will have transient, incomplete immunological control that is overwhelmed over time by viral escape mutations and immunological collapse (Bushman et al. 2011). This is why access to cART is so vital, in order to permit the body to restore partial immunological function by suppressing viral replication and stopping the mass destruction of CD4+ T lymphocytes.

Retroviruses have ribonucleic acid (RNA) as their genetic material, requiring the virus to use a reverse transcriptase enzyme to convert RNA into deoxyribonucleic acid (DNA). The DNA can then integrate into the host cell genome with the genetic instructions hijacking the cell’s protein manufacturing machinery to replicate HIV. While perhaps half of HIV-infected people with the infection have non-specific ‘flu’ symptoms, others may not be aware that they are ill at all (Cohen et al. 2011). Whether or not someone has experienced symptoms of acute HIV infection, in the following years, HIV-infected people do not feel ill and may transmit HIV for many years until diagnosed and treated or until illness and death.

Given that most HIV disease is asymptomatic, routine HIV testing must be promoted to identify asymptomatic disease. That screening of at-risk people is a mainstay of diagnosis and prevention is analogous to the disease control strategy for STIs and tuberculosis (Reid et al. 2004; Vermund et al. 2009). Within the pool of HIV-infected people, additional screening is essential, as for human papillomavirus-induced cervical precancerous lesions, human herpesvirus 8-induced Kaposi’s sarcoma lesions, *Mycobacterium tuberculosis*, and other conditions that are far more prevalent in HIV-infected than uninfected individuals.

Viral entry and replication

HIV uses a particular protein, CD4, to recognize cells. The CD4 protein serves as a receptor for fusion, entry, and infection. CD4 is short for ‘cluster of differentiation 4’, a terminology used in cell cytometry and immunology, representing a surface glycoprotein on key cells that provide immunological surveillance, namely T-helper lymphocytes, macrophages, monocytes, and dendritic cells. In humans, this protein is encoded by a *CD4* gene that, if mutated, may reduce susceptibility to infection. The HIV-1 uses

its protruding viral envelope protein known as gp120 to bind to CD4; gp stand for glycoprotein and 120 represents the molecular weight of this particular protein. HIV must bind to a CD4 receptor, creating a conformational shift in the gp120 that enables the virus to bind to chemokine co-receptors expressed on the host cell. Two types of co-receptors are used by HIV. One is termed CCR5 or C-C chemokine receptor type 5 that is coded by the human CCR5 gene. The other is known as CXCR-4 or C-X-C chemokine receptor type 4 (also known as fusin), a protein encoded by the CXCR4 gene. Once gp120-CD4 engagement has permitted viral docking with one of these two beta chemokine receptors, a structural change then occurs in viral protein gp41 (together, gp120 and gp41 make up gp160), enabling HIV to insert its fusion peptide into the CD4+ cell. HIV then fuses with the host cell membrane. CD4's primary function is a vital one, namely serving to assist T-cell receptors (TCR) on antigen-presenting cells (Wilens et al. 2012). That HIV lives in, and takes over, the machinery of the CD4+ T cell is much like the legend of the Greek soldiers within the Trojan horse, destroying the very cell that is designed to help defend against outside invaders.

Viral variation and evolution

HIV-1 has many variants, referred to as subtypes or clades, due to recombinant viruses generated through co-circulation of different viruses. High recombination and mutation rates result in the generation of circulating recombinant forms, or 'CRFs' (Kalish et al. 2004; Vermund and Leigh-Brown 2012). Over decades of viral expansion, the genetic complexity of HIV has increased globally such that over 40 CRFs have been recognized as of 2011. HIV-1 genetic diversity is greatest in west-central Africa where hunters of chimpanzees may have been infected with an HIV-precursor in the early twentieth century when they captured, killed, and skinned their primate 'bushmeat'. It is thought that chimpanzee HIV antecedents entered human populations in central Africa in the 1930s, with only indolent human-to-human transmission (Sharp and Hahn 2010). Later, conditions of migration, urbanization, loss of sexual taboos, injection-related contaminations, and global travel facilitated entry of HIV into populations practising higher-risk activities (e.g. multiple sexual partners, sex work, anal sex, injecting drugs). In central Africa, most major clades have been isolated (represented by alphabet letters A through K) (Kalish et al. 2004). Many observers suggest that there are few major biological differences among HIV clades, though there is a suggestion that C clade may be more pathogenic (Novitsky et al. 2011). Viral diversity continues to emerge and may be due to stochastic variations from founder infections with subsequent transmission within vulnerable populations (Rambaut et al. 2004; Hemelaar et al. 2011). Dating of divergence events can be estimated using 'molecular clocks' (Lewis et al. 2008). It appears that a divergence of major clades occurred in central Africa in the mid-twentieth century (Korber et al. 2000). Now that phylogenetic approaches permit estimations of sequence evolution rates, we can also use these estimates as parameters for epidemic modelling of sexual and other transmission networks (Vermund and Leigh-Brown 2012). Given that the world now confronts tremendous HIV genetic diversity, also driven by antiretroviral drug pressures, viral diversity is a principal challenge for future vaccine and antiretroviral drug development (Kalish et al. 2004; Takebe et al. 2010).

Current therapy and prognosis

Development of antiretroviral drugs

The scientific achievement represented by the discovery and development of antiretroviral drugs is among the great stories of applied scholarship in the late twentieth century (Broder 2010). The first discovered antiretroviral drug was zidovudine (ZDV) (also called azidothymidine (AZT)), a thymine analogue in the drug family of nucleoside reverse transcriptase inhibitors (NRTIs) (Mitsuya et al. 1991). When zidovudine is present, its thymine mimicry results in reverse transcriptase mistakenly adding it to the DNA strand; reverse transcription is then terminated since the zidovudine moiety does not accept the next nucleotide being added to the DNA.

Once ZDV was made available for clinical trials and then for commercial sale, there were early indications of clinical benefits in both clinical trials and also in larger population 'real-world use' conditions (Graham et al. 1992). However, viral mutation rates are high and drug-resistant strains emerged quickly, severely limiting the duration of single drug benefit (Anonymous 1994; Gardner et al. 1998). When new NRTI drugs were developed, dual therapy proved superior to monotherapy, but resistant viruses still emerged; the revolutionary change occurred with the advent of new classes of antiretroviral drugs that attacked the virus at different stages of its life cycle. Using cART, many patients who were adherent to their cART regimens could suppress HIV replication indefinitely. Current guidelines are permissive of a variety of alternative cART regimens (Thompson et al. 2010). In settings with adequate resources, nearly everyone with a detectable HIV viral load is recommended to be treated, regardless of CD4+ cell counts (Tables 8.13.1 and 8.13.2). Unfortunately for patients and for their uninfected sexual partners, low- and middle-income countries are typically limited to starting therapy at the threshold of WHO clinical status 3 or 4 and/or CD4+ cell counts <350/microlitre, or may even start at a lower threshold like <250 cells/microlitre, due to resource constraints. As this chapter goes to press, the WHO is changing its therapeutic guidelines to recommend cART for all people with CD4+ cell counts <500/microlitre, recommending consideration of treating even people with higher CD4+ cell counts, so-called universal test and treat, to benefit the patient and to reduce transmission to others.

Licensed antiretroviral therapy

There are six licensed classes of antiretroviral drugs (Table 8.13.3). Among the NRTI drugs, zidovudine, emtricitabine (FTC), lamivudine (3TC), abacavir (ABC), tenofovir disoproxil fumarate (TDF), didanosine (ddI or dideoxyinosine), and stavudine (d4T) are all in use. Stavudine has an unfavourable profile of side effects, but is still (as of early 2013) used widely in low-income countries due to its low generic cost. Non-nucleoside reverse transcriptase inhibitors (NNRTI) include efavirenz (EFV), both immediate- and extended-release forms of nevirapine (NVP), delavirdine (DLV), and newer drugs rilpivirine and etravirine.

Protease inhibitors (PIs) are often boosted with another protease inhibitor, ritonavir, to inhibit a cytochrome P450-3A4 (CYP3A4), a liver enzyme that metabolizes protease inhibitors. Ritonavir boosting both increases efficacy and reduces side effects of other PIs. PIs include amprenavir (APV), tipranavir (TPV), indinavir (IDV), saquinavir mesylate (SQV), lopinavir (LPV), ritonavir

Table 8.13.1 Preferred and alternative antiretroviral regimens for antiretroviral therapy-naïve patients

Preferred regimens	
Regimens with optimal and durable efficacy, favourable tolerability and toxicity profile, and ease of use. The preferred regimens for non-pregnant patients are arranged by chronological order of FDA approval of components other than nucleosides and, thus, by duration of clinical experience.	
	Comments
NNRTI-based regimen: • EFV/TDF/FTC ^a (AI) PI-based regimens (in alphabetical order): • ATV/r + TDF/FTC ^a (AI) • DRV/r (once daily) + TDF/FTC ^a (AI) INSTI-based regimen: • RAL + TDF/FTC ^a (AI)	• EFV is teratogenic in non-human primates. A regimen that does not include EFV should be strongly considered in women who are planning to become pregnant or who are sexually active and not using effective contraception. • TDF should be used with caution in patients with renal insufficiency. • ATV/r should not be used in patients who require >20 mg omeprazole equivalent per day.
Alternative regimens	
Regimens that are effective and tolerable, but have potential disadvantages when compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.	
	Comments
NNRTI-based regimens (in alphabetical order): • EFV + ABC/3TC ^a (BI) • RPV/TDF/FTC ^a (BI) • RPV + ABC/3TC ^a (BIII) PI-based regimens (in alphabetical order): • ATV/r + ABC/3TC ^a (BI) • DRV/r + ABC/3TC ^a (BII) • FPV/r (once or twice daily) + ABC/3TC ^a or TDF/FTC ^a (BI) • LPV/r (once or twice daily) + ABC/3TC ^a or TDF/FTC ^a (BI) INSTI-based regimen: • EVG/COBI/TDF/FTC ^a (BI) • RAL + ABC/3TC ^a (BIII)	• RPV is not recommended in patients with pretreatment HIV RNA >100,000 copies/mL • Higher rate of virologic failures reported in patients with pre-ART CD4 count <200 cells/mm ³ who are treated with RPV + 2NRTI • Use of PPIs with RPV is contraindicated • ABC should not be used in patients who test positive for HLA-B*5701 • Use ABC with caution in patients with known high risk of CVD or with pretreatment HIV RNA >100,000 copies/mL • Once-daily LPV/r is not recommended for use in pregnant women • EVG/COBI/TDF/FTC should not be started in patients with an estimated CrCl < 70 mL/min, and should be changed to an alternative regimen if the patient's CrCl falls below 50 mL/min • COBI is a potent CYP 3A inhibitor. It can increase the concentration of other drugs metabolized by this pathway • EVG/COBI/TDF/FTC should not be used with other ARV drugs or with nephrotoxic drugs

^a 3TC may substitute for FTC or vice versa. The following combinations in the recommended list in the table are available as coformulated fixed dose combinations: ABC/3TC, EFV/TDF/FTC, EVG/COBI/TDF/FTC, LPV/r, RPV/TDF/FTC, TDF/FTC, and ZDV/3TC.

3TC = lamivudine, ABC = abacavir, ART = antiretroviral therapy, ARV = antiretroviral, ATV/r = atazanavir/ritonavir, COBI = cobicistat, CrCl = creatinine clearance, CVD = cardiovascular disease, DRV/r = darunavir/ritonavir, EFV = efavirenz, EVG = elvitegravir, FDA = Food and Drug Administration, FPV/r = fosamprenavir/ritonavir, FTC = emtricitabine, INSTI = integrase strand transfer inhibitor, LPV/r = lopinavir/ritonavir, NNRTI = non-nucleoside reverse transcriptase inhibitor, NRTI = nucleoside reverse transcriptase inhibitor, PI = protease inhibitor, PPI = proton pump inhibitor, RAL = raltegravir, RPV = rilpivirine, RTV = ritonavir, TDF = tenofovir disoproxil fumarate, ZDV = zidovudine.

Rating of recommendations: A = Strong; B = Moderate; C = Optional.

Rating of evidence: I = Data from randomized controlled trials; II = Data from well-designed non-randomized trials or observational cohort studies with long-term clinical outcomes; III = Expert opinion.

Reproduced from Panel on Antiretroviral Guidelines for Adults and Adolescents, *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*, Department of Health and Human Services, 2013 version, available at <http://aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>.

(RTV), fosamprenavir calcium (FOS-APV), darunavir, atazanavir sulphate (ATV), and nelfinavir mesylate (NFV).

Three newer classes have single licensed drugs in each class, as of 2011, though more will be licensed in the future (Table 8.13.3). Raltegravir works to inhibit integrase, and is called an integrase strand transfer inhibitor. Maraviroc is a CCR5 blocker and inhibits viral entry, though it does not work against CXCR4 receptor strains of HIV. The fusion inhibitor is enfuvirtide (T-20), a costly drug given subcutaneously twice daily, used only for 'salvage therapy' of people with extensively drug-resistant HIV in high-income settings.

Some drugs are specifically formulated for paediatric use (US Food and Drug Administration 2014b). Availability of paediatric

formulations often lags, by years sometimes, the licensure of drugs suitable for adult consumption, a serious problem for the care of children with HIV infection (Dionisio et al. 2007). Antiretroviral chemotherapy principles are similar for adults and children, but the availability of paediatric formulations sometimes skews therapeutic decision making.

Many drugs are licensed generics in the US (US Food and Drug Administration 2014c). The generic market is expanding, and not all of the products have been through the FDA licensure process. The US FDA has approved a number of drugs for use in the PEPFAR in Africa, Asia, and the Caribbean (US Food and Drug Administration 2014d). The use of generics in PEPFAR has reduced costs and increased efficiency of programmes, but

Table 8.13.2 Other antiretroviral regimens for antiretroviral therapy-naïve patients

Regimens that may be selected for some patients but are less satisfactory than preferred or alternative regimens listed in Table 8.13.1	
	Comments
NNRTI-based regimen: • EFV + ZDV/3TC ^a • NVP + (ABC/3TC ^a or TDF/FTC ^a or ZDV/3TC ^a) • RPV + ZDV/3TC ^a PI-based regimens: • (ATV or ATV/r or DRV/r or FPV/r or LPV/r or SQV/r) + ZDV/3TC ^a • ATV + ABC/3TC ^a • SQV/r + (ABC/3TC ^a or TDF/FTC ^a) INSTI-based regimen: • RAL + ZDV/3TC ^a CCR5 antagonist-based regimens: • MVC + (ABC/3TC or TDF/FTC or ZDV/3TC ^a)	<ul style="list-style-type: none"> • NVP should not be used in patients with moderate to severe hepatic impairment (Child–Pugh B or C). • NVP should not be used in women with pre-ART CD4 count > 250 cells/mm³ or in men with pre-ART CD4 count > 400 cells/mm³ • Use NVP and ABC together with caution; both can cause HSRs within the first few weeks after initiation of therapy • ZDV can cause bone marrow suppression, myopathy, lipoatrophy, and rarely lactic acidosis with hepatic steatosis • ATV/r is generally preferred over unboosted ATV • Perform tropism testing before initiation of therapy with MVC. MVC may be considered in patients who have only CCR5-tropic virus • SQV/r was associated with PR and QT prolongation in a healthy volunteer study. Baseline ECG is recommended before initiation of SQV/r • SQV/r is not recommended in patients with: <ul style="list-style-type: none"> • pretreatment QT interval > 450 msec • refractory hypokalaemia or hypomagnesaemia • concomitant therapy with other drugs that prolong QT interval • complete AV block without implanted pacemaker • risk of complete AV block

^a 3TC may be substituted with FTC or vice versa.

3TC = lamivudine, ABC = abacavir, ART = antiretroviral therapy, ATV = atazanavir, ATV/r = atazanavir/ritonavir, AV = atrioventricular, DRV/r = darunavir/ritonavir, ECG = electrocardiogram, EFV = efavirenz, FPV/r = fosamprenavir/ritonavir, FTC = emtricitabine, HSR = hypersensitivity reaction, INSTI = integrase strand transfer inhibitor, LPV/r = lopinavir/ritonavir, msec = millisecond, MVC = maraviroc, NNRTI = non-nucleoside reverse transcriptase inhibitor, NVP = nevirapine, PI = protease inhibitor, RAL = raltegravir, RPV = rilpivirine, RTV = ritonavir, SQV/r = saquinavir/ritonavir, TDF = tenofovir disoproxil fumarate, ZDV = zidovudine.

Reproduced from Panel on Antiretroviral Guidelines for Adults and Adolescents, *Guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*, Department of Health and Human Services, 2013 version, available at <http://aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>

took a long time to negotiate, given the reluctance of Western pharmaceutical manufacturers to forgo perceived patent rights (Marques et al. 2005; Holmes et al. 2010). There are still daunting fiscal, regulatory, and operational challenges in obtaining the newest antiretroviral drugs for the global market (Waning et al. 2010).

Current recommended regimens

As of 2012, recommended components of initial antiretroviral regimens include (Thompson et al. 2010):

- ♦ Tenofovir (TDF)/emtricitabine (FTC), two NRTIs that are available as fixed-dose combination alone and also available with efavirenz, an NNRTI that is suitable for cART. Advantages of TDF/FTC are once-daily dosing and a high genetic barrier to resistance (TDF, not FTC). Side effects are not prominent, but include renal dysfunction and decreased bone mineral density associated with TDF.
 - An alternative is the combination of abacavir/lamivudine that is also once daily in a fixed-dose combination of two NRTI drugs. However, this combination has weaker antiviral efficacy in treatment-naïve patients with baseline HIV-1 RNA greater than 100 000 copies/mL than TDF/FTC. Abacavir has cardiovascular side effects and screening for HLA-B*5701 is advisable to reduce risk of abacavir hypersensitivity.

- ♦ To complete the cART regimen, either TDF/FTC or abacavir/lamivudine should be complemented with the NNRTI, efavirenz. HIV can mutate easily to evade NNRTI drugs so efavirenz resistance occurs very rapidly outside the context of cART. Alternatives to efavirenz are indicated for patients with major psychiatric illness, in their first trimester of pregnancy, or for women with an intention to become pregnant.
- ♦ Atazanavir boosted with ritonavir (both protease inhibitors) is a once-daily alternative as the backbone of a cART regimen. It leaves open options for future regimens as it can be used with NRTIs, preserving the use of NNRTIs for a later date when they might be needed. There is less lipidogenic potential than when lopinavir boosted with ritonavir is used. Use can be complicated by hyperbilirubinaemia, need for acid-reducing agents, and risk of nephrolithiasis.
- ♦ Darunavir boosted with ritonavir (both protease inhibitors) is another once-daily alternative as the backbone of a cART regimen in treatment-naïve patients. It is superior to lopinavir boosted with ritonavir.
- ♦ Raltegravir is an integrase inhibitor given twice daily. It has low potential to interact with other drugs, which is an advantage in its use. HIV can mutate quickly to evade this drug.
- ♦ Lopinavir boosted with ritonavir is a co-formulated pair of protease inhibitors that is heat stable and can be given once

Table 8.13.3 Antiretroviral drugs used in 2013 in the treatment of HIV infection, with licensure date at the Food and Drug Administration

Multi-class combination products		
Brand name™	Generic name	Approval date
Atripla	Efavirenz, emtricitabine and tenofovir disoproxil fumarate	2006
Complera	Emtricitabine, rilpivirine, and tenofovir disoproxil fumarate	2011
Nucleoside reverse transcriptase inhibitors (NRTIs)		
Combivir	Lamivudine and zidovudine	1997
Emtriva	Emtricitabine, FTC	2003
Epivir	Lamivudine, 3TC	1995
Epzicom	Abacavir and lamivudine	2004
Retrovir	Zidovudine, azidothymidine, AZT, ZDV	1987
Trizivir	Abacavir, zidovudine, and lamivudine	2000
Truvada	Tenofovir disoproxil fumarate and emtricitabine	2004
Videx EC	Enteric coated didanosine, ddl EC	2000
Videx	Didanosine, dideoxyinosine, ddl	1991
Viread	Tenofovir disoproxil fumarate, TDF	2001
Zerit	Stavudine, d4T	1994
Ziagen	Abacavir sulphate, ABC	1998
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)		
Edurant	Rilpivirine	2011
Intelence	Etravirine	2008
Rescriptor	Delavirdine, DLV	1997
Sustiva	Efavirenz, EFV	1998
Viramune (immediate release)	Nevirapine, NVP	1996
Viramune XR (extended release)	Nevirapine, NVP	2011
Protease inhibitors (PIs)		
Agenerase	Amprenavir, APV	1999
Aptivus	Tipranavir, TPV	2005
Crixivan	Indinavir, IDV	1996
Invirase	Saquinavir mesylate, SQV	1995
Kaletra	Lopinavir and ritonavir, LPV/RTV	2000
Lexiva	Fosamprenavir calcium, FOS-APV	2003
Norvir	Ritonavir, RTV	1996
Prezista	Darunavir	2006
Reyataz	Atazanavir sulphate, ATV	2003
Viracept	Nelfinavir mesylate, NFV	1997
Fusion inhibitor		
Fuzeon	Enfuvirtide, T-20	2003
Entry inhibitor—CCR5 co-receptor antagonist		
Selzentry	Maraviroc	2007
HIV integrase strand transfer inhibitor		
Isentress	Raltegravir	2007

Adapted from U.S. Food and Drug Administration, *Antiretroviral Drugs Used in the Treatment of HIV Infection: Drugs Used in the Treatment of HIV Infection*, available from <http://www.fda.gov/ForConsumers/byAudience/ForPatientAdvocates/HIVandAIDSActivities/ucm118915.htm>.

daily. Side effects include hyperlipidaemia and gastrointestinal symptoms.

- ◆ Fosamprenavir boosted with ritonavir represent two protease inhibitors with a profile similar to lopinavir/ritonavir, useful when other preferred drugs are not tolerated.
- ◆ Maraviroc is a CCR5 antagonist that targets the host protein CCR5 viral co-receptor. Since one needs to ensure that CXCR4 virus is not present, one needs to perform a costly viral tropism assay before use. With limited clinical experience in treatment-naïve patients, there are theoretical reasons to avoid its use in other than multiple drug failure patients who do not have CXCR4 receptor HIV strains circulating (Parra et al. 2011).
- ◆ Enfuvirtide is an HIV fusion inhibitor, used in combination therapy for 'salvage' therapy in patients with multidrug-resistant HIV. The peptide is biomimetic, that is, designed to mimic components of the HIV-1 fusion machinery, and the drug displaces normal fusion components to prevent successful virus–cell fusion. Enfuvirtide therapy is extremely costly and its inconvenient dosing (subcutaneously twice daily) regimen further limits its global relevance.

Challenges in patient care

Patient management issues are complex for HIV disease (Tables 8.13.1 and 8.13.2). Rather than the death sentence for so many in the pre-treatment era, HIV disease is now a chronic, manageable disease. It requires HIV testing, linkage to care, cART availability, national guidelines permitting cART administration, and adherence to lifelong therapeutic regimens. In the United States, only a quarter of people infected with HIV are on suppressive cART, showing how inadequate current systems are to meet the full need (Burns et al. 2010; CDC 2011; Gardner et al. 2011). In low- and middle-income countries, it is likely that fewer than 10 per cent of people infected with HIV are on cART with successful viral suppression. Special challenges exist with co-morbidities that may inhibit proper healthcare access and/or adherence to cART regimens. These include mental health problems such as depression, and substance use including opiates, stimulants, and alcohol (Altice et al. 2010; Gonzalez et al. 2011; Nel and Kagee 2011). In addition, stigmatized people who do not feel comfortable 'coming out' into the mainstream of clinical care may not reach care, or be retained in care; this is thought to be an important driver of the epidemic in black MSM in the United States, for example (Millett et al. 2006; Mimiaga et al. 2009; El-Sadr et al. 2010; Vermund et al. 2010; Millett et al. 2011; Lauby et al. 2012). Adolescents present special challenges in care and adherence rates have been suboptimal in this population (Murphy et al. 2000; Vermund et al. 2001; Murphy et al. 2002; Ding et al. 2009; Reisner et al. 2009). Children in care depend on the capabilities of their parents or guardians; many children have been orphaned and some do not know that they are HIV infected, making it difficult for them to participate in their ongoing care (Zhao et al. 2007; Vaz et al. 2011).

ART itself has an array of complications that require recognition and management (Thompson et al. 2010). PIs are associated with lipid abnormalities and cardiovascular risk. Efavirez is contraindicated in pregnancy. NRTIs can have serious, albeit rare, lactic acidosis. Stavudine can cause severe peripheral neuropathies. Beyond the scope of this chapter, these side effects require

preventive and therapeutic management from a clinician experienced in HIV drug regimens and their alternatives.

The tremendous impact on morbidity and mortality of cART in high-income countries has been well documented (Lundgren and Mocroft 2006; Walensky et al. 2006; Lauby et al. 2012). Similar benefits are seen in low- and middle-income countries, but they depend on the programmatic efficiencies, resources available from PEPFAR, the Global Fund to Fight AIDS, Tuberculosis and Malaria, local Ministries of Health, and the ability of programmes to find, recruit, and retain HIV-infected people in cART-based care (Table 8.13.4) (Rosen et al. 2005; Schwartlander et al. 2006). Scaling up of programmes has been both challenging and inspiring; new models for the management of chronic diseases in resource-limited settings are now extant, offering promise for a wide variety of diseases requiring ongoing care for their management (Stringer et al. 2006; Bolton-Moore et al. 2007; Abimiku and Institute of Human Virology 2009; Morris et al. 2009; Vergara et al. 2009; Ciampa et al. 2011; Moon et al. 2011).

Case study in prevention, care, and treatment: YRG CARE in India

While prevention, care, and treatment challenges are daunting in developing countries, there are examples of highly successful programmes that have engaged thousands of infected people and sometimes hundreds of thousands of people in prevention. One such programme is the Y.R. Gaitonde Center for AIDS Research and Education (YRG CARE) in Chennai, Tamil Nadu, India.

An Indian-owned and operated non-profit medical and research institution, the internationally recognized YRG CARE was founded in 1993 by Dr Suniti Solomon whose team identified the first case of HIV in India (Simoes et al. 1987). YRG CARE offers a wide array of HIV prevention, care, and treatment services.

YRG CARE's vision is that people with HIV and AIDS and their families live with dignity, and that there are no new infections. YRG CARE's mission is to respond to prevention, care, and research needs of the nation of India. YRG CARE offers services without judgement or discrimination, and is known for its client-centred approach, its comprehensive service portfolio, its commitment to community, and its respect for the dignity and privacy of individuals.

YRG CARE reaches out to and is committed to improving the lives of thousands of men, women, and children infected or affected by HIV in India through a wide array of prevention, education, care, and treatment services. It is also committed to conducting clinical, laboratory, and social research, building a core of young researchers, and offering training to other service providers. The centre is now focused on user-friendly clinics for MSM and PWID, adopting harm reduction approaches in community engagement (Solomon et al. 2008, 2010).

YRG CARE builds awareness about HIV infection and promotes safe behaviours in schools, colleges, STD clinics, workplaces, communities, and through helplines. As poverty, intimate partner violence, and poor perception of HIV risks make prevention especially difficult for women in India, YRG CARE promotes primary prevention amongst women through education, innovative livelihoods and sensitizing men to become change agents in the community (YRG CARE).

YRG CARE provides access to an affordable continuum of care that improves the quality of life of people living with HIV/AIDS.

Table 8.13.4 Some essential elements needed to nurture successful and complete transition of HIV care and treatment programmes to national governments and local organizations, with long-term sustainability

Essential elements	Goals
Health workforce development	Increase the numbers of healthcare providers, increasing coverage for rural care; task shifting to nurses, clinical officers, laboratory and pharmacy technicians, care partners, and community health workers
Integration of services	Enable HIV/AIDS care and treatment to be handled by sustainable primary care programmes, with key linkages to sexually transmitted infection and tuberculosis control, and family planning, for example
Physical infrastructures	Empower communities to access basic electricity, water, medical waste disposal, and clinic space for physical examinations, patient education/waiting, laboratory, and basic surgery/anaesthesia
Pharmacy logistics systems	Ensure that inventory management, shipping, and storage systems avoid stock-outs of supplies (e.g. test kits, blood draw equipment) and antiretroviral, antibiotic, and other drugs
Laboratory development	Decentralize laboratory work, as much as possible and affordable, with point-of-care diagnostic tests
Quality of care and iterative evaluation	Build sustainable quality improvement research and systems improvement efforts into HIV care programmes
Hub-and-spoke models of care	Bring primary and HIV/AIDS care closer to people who are remote from major clinical services
Data management systems	Build sustainable, affordable electronic medical record systems to harmonize systems created for the emergency HIV response
Community engagement to support programmes	Implement innovative models of outreach, retention, and adherence support in the community, using the inherent strengths of patient-to-patient and family-to-patient support as a form of task shifting
Cultural changes in the health sector	Train staff and reform procedures to protect patient confidentiality and privacy, provide more respectful, client-friendly services, and ensure that all communications are in languages spoken by patients
Management and administration	Train and capacitate health systems to use modern business practices for financial and logistical management
Long-term funding	Reset national and international priorities to emphasize health and development, rather than disparate economic development and unproductive government investments such as war and armaments

Adapted with permission from Lippincott Williams and Wilkins/Wolters Kluwer Health: Vermund SH et al., Transitioning HIV care and treatment programs in southern Africa to full local management, *AIDS*, Volume 26, Issue 10, pp. 1303–1310, Copyright © 2012 Lippincott Williams & Wilkins, Inc.

Services include HIV voluntary counselling and testing (VCT); primary healthcare; dental care; eye care; highly active antiretroviral therapy (HAART) (Solomon et al. 2013); home care; psychosocial counselling, adherence support, and nutritional counselling for clients, couples, and families; PMTCT and other ob-gyn surgical services; radiology referral services; subsidized pharmacy; matrimonial (match making) services; alternative insemination for discordant couples; and health education and treatment literacy for clients and their personal care givers. As of early 2013, over 18,000 people living with HIV have registered at its clinics for services.

YRG CARE offers state-of-the-art laboratory services, including STI investigations, OI diagnosis, and biochemical evaluations for patient services as well as for clinical trials. The laboratory is accredited by India's National Accreditation Board for Testing and Calibration Laboratories (NABL), Government of India, that adheres to international ISO/IEC standards (International Organization for Standardization and the International Electrotechnical Commission). Given YRG CARE's participation in international clinical trials, its labs are also certified by the Division of AIDS of the National Institute of Allergy and Infectious Diseases of the US National Institutes of Health. The laboratory is designated as the International Regional HIV-1 Genotyping Laboratory by the Division of AIDS (since 2006) and has been recognized as an International Regional Tuberculosis Diagnostic Laboratory for Division of AIDS clinical trials protocols. The laboratory is affiliated with the nearby University of Madras and has multiple candidates who are pursuing PhD degrees in Medical

Microbiology. YRG CARE lab experts have contributed to several national and WHO (SEARO) diagnostic guidelines.

YRG CARE offers training for clinicians, obstetricians and gynaecologists, laboratory scientists and technologists, health-care workers, social workers, and counsellors in their respective fields relating to HIV prevention and management. This includes short-term trainees from throughout India and from other Asian nations.

With a modest beginning in research in the late 1990s, YRG CARE has since emerged as a pioneer in research on HIV and related co-infections, meeting the highest standards of ethics and regulatory compliance, in partnership with global leaders (Kumarasamy et al. 2003, 2005; Solomon et al. 2009). Running across its clinic, community, and laboratory clusters, these research studies answer questions that are most important and relevant to India in the fields of epidemiology, laboratory, prevention, natural history, and treatment outcomes. The Chennai International Clinical Trials unit of YRG CARE is one of the clinical research sites for the Division of AIDS clinical trials for both therapy and prevention. YRG CARE's proactive Community Advisory Board promotes community participation in study design, implementation, literacy efforts and follow-up care.

The early days of the epidemic in India witnessed tragic consequences of the disease unchecked by effective therapy or prevention. It was a period of poor understanding of the risks of caring for someone living with HIV—both by healthcare workers and society alike. Faced with rejection, people living with HIV lived without hope and died alone. It was a period of very low

prioritization of aspects of the global response that are a mainstay of intervention today—test, treat, support, and prevent. YRG CARE continues to lead the response to HIV in India in meaningful ways, introducing cutting-edge technologies in prevention, diagnosis, and care and championing compassionate advocacy to mitigate the impact of discrimination, stigma, and prejudice that is deep rooted in pockets of society. YRG CARE highlights are representative of what both non-governmental and governmental institutions have spearheaded globally in the HIV era:

- ◆ First voluntary counselling and testing (VCT) service in Southern India.
- ◆ First HIV education sessions in schools and colleges, a model now adapted and implemented by UNICEF and YRG CARE throughout Tamil Nadu state.
- ◆ First medical centre for people living with HIV/AIDS.
- ◆ Largest centre in terms of comprehensive HIV care and social support services for patients in the non-governmental sector.
- ◆ Extensive experience in antiretroviral therapy.
- ◆ A range of research projects including large population-based longitudinal trials (over 3500 participants) and Phase III clinical trials.
- ◆ State-of-the-art laboratory dedicated to HIV diagnosis, monitoring of HIV disease, and surveillance for antiretroviral drug resistance.
- ◆ Offers complete biological markers for community-based HIV field surveys.
- ◆ Recognized by the University of Madras as a centre for the pursuit of doctoral studies in microbiology.

YRG CARE is an organization that emerged with a new paradigm of care for Indians with a stigmatized infectious disease. Organizations throughout the world have embraced similar principles and strategies to reach out to disenfranchised groups and people who are infected or at-risk for HIV.

Elements of combination prevention

Evidence for efficacy of elements of combination prevention can come from observational data (as with male condoms or reduction in partner numbers) or from randomized clinical trials (RCTs; as with male circumcision or early treatment as prevention). Which elements might be considered essential for successful combination prevention are a matter of debate, but can be elucidated with decision-analysis and HIV transmission models (Tables 8.13.1 and 8.13.2). A consensus is emerging that combination prevention should be anchored on the use of cART given that infected people who receive and are adherent to their cART regimens can suppress HIV replication and reduce their infectiousness (Smith et al. 2012). At the time of this writing, Ministries of Health of LMIC typically limit their start of cART at the WHO recommended threshold of CD4+ cell counts less than 350/microlitre or WHO clinical status 3 or 4 (Stanecki et al. 2010). Some of the most resource-limited nations continue to authorize the start of cART at a lower threshold like less than 250 cells/microlitre, despite overwhelming evidence that this is too late for optimal clinical response (Moon et al. 2011). A large proportion of transmissions occur before patients reach the usual thresholds for ART

initiation, however, a rationale for treating at earlier CD4+ cell counts (or even universal ART for all HIV-infected people).

The HIV Prevention Trials Network 052 protocol (HPTN 052) was an RCT that assessed early initiation of cART at CD4+ cell counts of up to 550/microlitre, demonstrating both reduced transmission of HIV to sexual partners as well as clinical benefits to their infected partners on cART (Cohen et al. 2011). Hence it is disappointing that only 19–28 per cent (range of estimates) of Americans infected with HIV were on cART with successful suppression of HIV viral load (Burns et al. 2010; CDC 2011; Cohen et al. 2011; Gardner et al. 2011). Even if these are overly pessimistic estimates due to some ‘lost-to-follow-up’ patients possibly being in therapy elsewhere, the true rates of ART coverage and viral suppression are disappointing, in both high- and low-income nations (Geng et al. 2012; Shepherd et al. 2013).

In selected venues, ecological evidence of prevention benefits from cART is emerging (Das et al. 2010; Montaner et al. 2010). Ecological analyses in San Francisco, Vancouver, China, Taiwan, and KwaZulu-Natal have suggested that higher cART coverage may correlate with lower seroincidence rates (Fang et al. 2004; Das et al. 2010; Montaner et al. 2010; Tanser et al. 2012; Jia et al. 2013). However, it is unknown whether these correlations represent success of TasP or whether other factors are contributing (Vermund 2013).

Vancouver is a case in point. Investigators and public health officials have addressed prevention of HIV with needle/syringe exchange and opiate substitution therapy among Vancouver PWID at the same time that cART was being made available (Kerr et al. 2010). Hence, it is hard to disaggregate the prevention impact of needle/syringe exchange and expanded heroin addiction therapy from cART expansion or other factors. Western Europe is also a region of interest (Vermund and Leigh-Brown 2012). It is easy to speculate that easy access to HIV testing and widespread cART use within national health systems may have resulted in lowering HIV incidence rates in Western Europe, but it is hard to know whether other sociocultural factors or prevention efforts also made impacts. However, in the United Kingdom where access to testing and treatment is facilitated by the National Health System (NHS) with free services available to all, no reduction in the incidence of new infections in MSM has been noted to date, so interpreting European experiences is not always clear-cut.

The option of moving to *immediate* offering of ART—irrespective of CD4+ cell count is being supported by public health policy in San Francisco, Vancouver, New York City, and elsewhere. If HIV testing were expanded markedly and all people were treated shortly after diagnosis and successful virally suppressed, then fewer infectious people would be transmitting to others and the epidemic might decline. Whether this is possible is the topic of intense current investigation (Burns et al. 2010; Beyrer et al. 2011; Ciampa et al. 2012; Sahasrabudde et al. 2012; Vermund and Hayes 2013; Vermund et al. 2013a, 2013b).

Suboptimal cART coverage and viral suppression

In the United States, current systems fail to meet the full need of HIV-infected patients, many of whom have co-morbidities that inhibit full viral suppression (Burns et al. 2010; CDC 2011; Gardner et al. 2011). These may include substance use (e.g. drugs and/or alcohol), mental health problems, financial and health-care insurance challenges, transportation issues, and stigma/

disclosure challenges (Altice et al. 2010; Gonzalez et al. 2011; Nel and Kagee 2011). In LMICs, it is likely that fewer than 10 per cent of all infected people are successfully virally suppressed.

Stigmatized people who do not 'come out' may not reach medical care or be retained in care, as is the case with black MSM in the United States (Millett et al. 2006; Mimiaga et al. 2009; El-Sadr et al. 2010; Vermund et al. 2010; Millett et al. 2011; Lauby et al. 2012). Adolescents with HIV infection have demonstrated abysmal adherence rates in some studies, suggesting the need for services that include outreach and engagement (Murphy et al. 2000; Vermund et al. 2001; Murphy et al. 2002; Ding et al. 2009; Reisner et al. 2009). Children with HIV are dependent on their parents or guardians; many children have not had their HIV status disclosed to them and may not be participating actively in their ongoing care (Zhao et al. 2007; Vaz et al. 2011).

The gulf between current guidelines for high-income countries where all HIV-infected people are typically offered cART versus WHO and LMIC Ministries of Health that offer a smaller proportion of HIV-infected people cART (typically people under 350 CD4+ cells/microlitre) is worth highlighting. By definition, the latter policies have a larger pool of infected people who remain virally unsuppressed. If resources were obtained to treat all HIV-infected individuals (i.e. universal, immediate cART), the proportion of infectious people would decline. If a large enough pool of infectious people were made non-infectious, mathematical models suggest a decline in new infections (Baggaley and Fraser 2010; Wagner and Blower 2012; Cremin et al. 2013). It is not certain that a test-and-treat prevention strategy is feasible, acceptable, sustainable, and affordable (Shelton 2011; Vermund et al. 2013a). The most resource-limited LMICs depend on the programmatic resources available from PEPFAR and the Global Fund to Fight AIDS, Tuberculosis and Malaria; local Ministries of Health rarely have the resources to find, link, and retain HIV-infected people in cART-based care, with optimized adherence (Rosen et al. 2005; Schwartlander et al. 2006; Vermund et al. 2012). The long-term management of chronic diseases in LMICs is challenging; HIV investments may serve as a backbone for also addressing a wide variety of diseases requiring chronic management (Stringer et al. 2006; Bolton-Moore et al. 2007; Abimiku and Institute of Human Virology 2009; Morris et al. 2009; Vergara et al. 2009; Ciampa et al. 2011; Moon et al. 2011).

We also do not know whether a test-and-treat approach will have the postulated benefits in a real-world circumstance (Ciampa et al. 2012; Vermund and Hayes 2013; Vermund et al. 2013a, 2013b). Whether we can further enhance its benefits with other prevention modalities without overwhelming the public health and clinical systems is also unknown (Shelton 2011). While behaviour change is a component of all approaches, some combined interventions make sense in the context of certain epidemic circumstances, as with male circumcision in generalized epidemics and needle exchange where PWID drives transmissions.

Adapting for local epidemics

HIV is a disease based on patterns of human behaviour; hence, it is affected and modulated by stigma, discrimination, prejudice, fear, stress, depression, denial, and ignorance. Many have compared AIDS to the leprosy of the Bible when infected people were shunned and even banished. Since HIV is transmitted similarly to patterns for other sexual and blood-borne agents, it is subjected

to the same societal distress surrounding other STIs. HIV transmission is more likely in the face of multiple sexual partners (i.e. high mixing rates) and failure to use condoms, so people acquiring infection are typically judged by others (Vermund et al. 2009). However, we must put stigma into its modern perspective. While a major problem in most areas, especially perhaps in concentrated epidemics in marginalized risk-groups, there are also signs of 'normalization' of HIV as a public health problem in both higher-income and LMICs, including in southern Africa. We speculate that wider access to cART has contributed to an improving social environment for many people living with HIV.

Much progress has been made in the avoidance of iatrogenic and occupational parenteral transmission by unclean syringes and needles through single use technologies, serological screening of blood or blood products, and policies to reduce inadvertent needle sticks in an occupational healthcare setting. Progress, too, has been made in offering universal screening of pregnant women and the offering, uptake, and adherence to one of a variety of antiretroviral therapy options, pre-partum, intra-partum, or post-partum, to avoid mother-to-child transmission that can take place *in utero*, during delivery, or from breastfeeding, respectively (Fowler et al. 2010; Whitmore et al. 2010). Yet too often, successful programmes are not integrated and potential synergies for combination prevention are lost. If testing/treatment successes in PMTCT, say, could be expanded into the analogous treatment as prevention cascade for adults, we might well combine components of prevention into an integrated whole, with the kind of impact on incidence not often seen in the global pandemic.

Hepatitis B virus (HBV) is spread in ways reminiscent of HIV, though HBV is typically more communicable. Our tools for HBV control include active and passive immunization, tools that are not yet available for HIV control. In addition, HIV infection is not yet curable, such that people whose viral loads are not suppressed can transmit the infection for many years. Other STIs can also be spread via blood-borne routes (e.g. syphilis, hepatitis C virus (HCV), and human T-lymphotropic virus type 1 (HTLV-1)), but sexual routes are the dominant mode of transmission for most STIs, as with HIV. Co-infections of HIV are common for both blood-borne and sexually transmitted infections. The CD4+ T-lymphocyte tropism of HIV makes it unique among the STIs and its penchant for deep lymphoid tissue invasion and quiescence are the roots of its incurability.

Stigma, discrimination, poverty, and human rights

HIV spread is steeped in gender inequality, poverty, discrimination based on sexual preference and identity, and perverse public policies that exacerbate the epidemic, rather than control it. Though over three decades have passed since the detection of AIDS, infection with HIV is still perceived as a disease of 'others'—of those living on the margins of society, whose lifestyles are considered perverse or sinful (Bos et al. 2008; Altman et al. 2012). Despite excellent advances in the area of both prevention technologies and treatment of HIV/AIDS with innovative programming and inclusive policies, such judgemental and stigmatizing values result in discrimination and marginalization of vulnerable people, especially those living with HIV and their families in communities, workplaces, and healthcare settings.

Self-stigmatization amongst people living with HIV/AIDS is also high, which in turn results in self-isolation and diminishing

social relationships. This stigmatization affects prevention efforts and uptake of services. Individuals at risk will not access voluntary counselling and testing, and if tested positive will not follow up in care nor disclose to family. They often marry due to societal and cultural pressure and transmit HIV infection to their partners. This dynamic is especially apparent in communities with strong cultural pressures to have children, for example, India, where in many communities being barren is associated with greater stigma than is having HIV.

Culturally sensitive community-wide education is critical to reducing the effects of social stigma. Approaches that raise awareness about sexual identities and that raise self-esteem are also necessary to address the profound feelings of shame that marginalized communities experience.

A perspective on the role of stigma in fuelling the epidemic must recognize the fear that an HIV diagnosis still engenders among many. Yet the fact that increased HIV testing and adherence to cART-based care represents a sign of 'normalization' of HIV as a public health challenge in many countries, including some in southern Africa, where wider access to cART has probably contributed to HIV being seen more like other chronic diseases (Marum et al. 2012).

Stigma even extends to public policy and law. Perverse practices include the banning of or failing to support needle exchange for PWID in the United States before the Obama Administration (Lurie and Drucker 1997; Drucker 2012) or failing to provide ART in South Africa during the Mbeke Administration (Gow 2009). Russia's failure to legalize and promulgate clean needle distribution and opiate substitution therapy, the continued demonization of MSM in many African countries, and the insistence on ineffective 'abstinence only' educational investments in the United States are additional examples of policy gone awry (Underhill et al. 2007; Mathers et al. 2010; Burki 2012; Chin et al. 2012). In the face of the politicization of HIV/AIDS, policymakers failing to use existing tools to prevent HIV transmission are responsible for much preventable infection (Mahy et al. 2009). Failure to protect the blood supply early in the epidemic led to the infection of tens of thousands of blood and blood product recipients worldwide, especially people with haemophilia. The taboo of politicians, religious leaders, teachers, or even healthcare providers discussing sexual risk reduction frankly and clearly keeps issues of HIV prevention from being fully integrated into political, religious, and social discussions. This is unfortunate since some themes—delaying adolescent coital debut and reducing numbers of sexual partners, for example—are widely supported goals in nearly all circles and political philosophies.

While condoms are opposed by some due to a conviction that they may lead to higher risk sexual activities and/or that they may violate certain religious proscriptions against contraception, there is no strong evidence for the former view and support for the latter may be waning. For example, a major Catholic religious leader who previously opposed condom use stated in a 2010 book that 'there may be a basis in the case of some individuals, as perhaps when a male prostitute uses a condom, where this can be a first step in the direction of a moralization, a first assumption of responsibility' (Pope Benedict XVI and Seewald 2010). The religious leader later indicated that he also was referring to female prostitutes when he suggested that condom use may actually be a morally superior choice to prevent transmission to others. Such

changes in attitude can be influential in empowering at-risk people to protect themselves without going counter to religious views to which they may subscribe.

Failures in public policy have consequences. Modellers have quantified public policy failures, particularly the failure to provide clean needles and syringes for PWID in the United States from 1987 to 1995, estimating that an excess of between 4394 and 9666 infections, representing a third of incident PWID cases, was the result (Lurie and Drucker 1997). The attendant excess costs to the United States were US\$244–538 million. It will be a major stride in the HIV field if public health advocacy for evidence-based prevention could be the basis for HIV control policy and investment (Mathers et al. 2010).

Behaviour change

Even in the face of biomedical interventions such as TasP or voluntary medical male circumcision, behaviour change is an essential component of prevention interventions; for example, people must agree to and adhere to the given intervention. All by itself, however, behaviour change to reduce HIV incidence has not proven robust (Wetmore et al. 2010). In studies designed to enhance adherence to ART, for example, the impact of behavioural interventions has often been very contextual or transient (Barnighausen et al. 2011). The HIVNET 015 Project EXPLORE protocol in MSM in the United States sought to lower HIV incidence with an intensive ten-visit educational programme that included reinforcement sessions (Koblin et al. 2004). Investigators were disappointed with the 18.2 per cent reduction (95 per cent CI –4.7 to 36.0 per cent) in HIV incidence in the intervention group compared to a control group receiving a short intervention (Koblin et al. 2004). However, given that the benefits were even lower in substance users and people with mental health problems, this underscored the importance of attending to these co-morbidities in order to reduce HIV transmission (Colfax et al. 2004; Salomon et al. 2009).

For TasP, willingness to test for HIV, be linked to care, and adherence to cART to reduce infectiousness all require behavioural support. Pre-exposure prophylaxis (PrEP) using cART in seronegative people to prevent infection, and increased testing and linkage to cART requires high levels of adherence to be successful. 'Serosorting' is when HIV seropositive people have sex only with other infected people, and HIV-seronegatives seek other uninfected people for sex; this obviously requires a great deal of self-efficacy and motivation. Substance abuse treatment, including needle exchange, alcohol treatment, and opiate substitution therapy, as needed, depend on motivated and able clients. Contingency cash transfers are rewards for lowering risk behaviours, and depend on behaviour change.

Classic 'ABC' approaches of Abstinence/Be faithful/Condom advocacy are fully dependent upon behavioural change (Corsi and Booth 2008; Rotheram-Borus et al. 2009; Burns et al. 2010). The US CDC has published its evidence-based interventions for risk reduction in the United States; they are heavily behaviourally-based (Lyles et al. 2006; Margaret Dolcini et al. 2010). Abstinence-only education has been unsuccessful in reducing risk and was paradoxically associated with higher pregnancy rates than more comprehensive educational approaches that included STI prevention advocacy based on abstinence, partner reduction, and condom use (Underhill et al. 2007; Chin et al. 2012). It is the consensus in the HIV scientific community that 'ABC' principles are vital

guides for public health intervention, but are better bundled with biomedical prevention approaches; alone behavioural change approaches are not likely to stop the global pandemic (Holmes 2004; Rotheram-Borus et al. 2009; Vermund et al. 2009, 2010, 2013b; Kurth et al. 2011; Vermund and Hayes 2013).

Linked to behaviour change, but worthy of separate consideration are the so-called structural interventions. This involves changing laws, policies, or other societal norms to reduce risk behaviour. Raising cigarette taxes to reduce tobacco use among youth or banning cigarette smoking in indoor spaces where the public has access are examples of structural interventions. If schools were improved, school fees eliminated as obstacles to full attendance, and after-school opportunities for youth were promulgated, this might be considered a structural change to seek to reduce substance abuse in higher income nations and the exchange of sexual services for money to attend school as happens in many LMICs. A law requiring all commercial transient lodgings (hotels, etc.) to provide in-room condoms would be another example of a structural intervention. Large scale programmes to offer universal testing in saturation volumes, incentives to link people with HIV to care, near-universal use of cART for all HIV-infected people, and community partnerships to maximize clinic attendance and cART adherence are the backbone of TasP programmes that, while still depending on behavioural adherence, would be enhanced considerably if a structural context could be promulgated by policymakers of routine, widespread, opt-out testing.

Packages of tools for combination prevention

'Magic bullets' have not worked to control the epidemic on their own, with the possible exceptions of needle exchange for PWID and blood screening for blood banks. Even if we had a proven, effective vaccine for HIV, vaccination would still require multiple voluntary visits to optimize immunization along with large-scale population mobilization and programme expansion for children, adolescents, and/or adults, depending on vaccine characteristics (e.g. durability of protection). Combination prevention packages must vary to target those at-risk people who are at highest risk in a given epidemiological context. If the local epidemic is being driven by PWID, then needle exchange and addiction treatment will be the best strategies, along with primary prevention of drug abuse. If sex work is a principal driver of a local epidemic, community and political mobilization of sex workers and their employers (e.g. brothel owners, pimps, madams) will be needed to ensure effective STI screening and treatment, to promote universal condom use, and perhaps to provide PrEP. Other efforts to offer sex workers a way out of the profession through protection and job retraining and job placement, as well as to control sexual trafficking, can help protect the women who are aided, and may or may not reduce prostitution or HIV incidence overall.

Some interventions have far stronger levels of evidence of efficacy to reduce HIV transmission (infectiousness) or acquisition (susceptibility) than others. Among these are voluntary medical male circumcision (VMMC) with compelling observational data supported by three definitive and remarkably consistent RCTs (Auvert et al. 2005; Bailey et al. 2007; Gray et al. 2007). ART for prevention was begun as a concept with the definitive demonstration of prevention of maternal-to-child transmission (PMTCT) with ART dating from 1994 (Connor et al. 1994). Observational data from 2000 to 2001 and an incidental finding in a clinical trial

in 2010 suggested that cART would reduce sexual transmission (Quinn et al. 2000; Fideli et al. 2001; Donnell et al. 2010). Finally, the HPTN 052 RCT, over a decade in the making, demonstrated early use of cART as a major tool to reduce infectiousness and sexual transmission to partners, while clinically benefiting the infected people as well (Cohen et al. 2011).

Other strategies are logical as adjunctive tools for HIV prevention, but are less consistently beneficial in RCTs. STI control based on syndromic management worked very well in one Tanzanian epidemic context to reduce HIV transmission, but has failed in other epidemic contexts and other treatment approaches (Korenromp et al. 2005). PrEP has had a mixed success: tenofovir-containing PrEP (cART among HIV-seronegative at-risk people) was successful in CAPRISA 004 (topical microbicide for women), iPrEx (MSM) and Partners PrEP and TDF-2 studies (heterosexual men and women), but not in the large VOICE trial (heterosexual women) or the FemPrEP studies (heterosexual women) (Abdool Karim et al. 2010; Grant et al. 2010; Celum and Baeten 2012). The Thai vaccine prime-boost strategy published in 2009 was partially effective; however, the vaccine companies did not seek licensure for marketing of either the prime or boost products, given their very modest effects (Rerks-Ngarm et al. 2009). Nonetheless, as better oral and vaginal PrEP/microbicide and vaccine products are developed, they may be added as future components to the therapeutic armamentarium. Given that PrEP is a tool for use in seronegative people and TasP a tool for use in seropositive people, work is needed to assess how these might be combined to maximize potential HIV impact at the community level.

When RCT data are not available, observational data are used to make judgements as to likely efficacy. Evidence of male condom efficacy is confirmed by effectiveness studies (Holmes 2004). Evidence for efficacy and effectiveness of female condoms is inconsistent, but they have been reported helpful in selected contexts (Gallo et al. 2012). Of certain utility, but not backed up by RCT evidence are needle exchange for drug users and opioid substitution therapy for PWID (Kerr et al. 2010). Also convincing are the use of contraception for HIV-infected women to reduce unintended pregnancies and HIV infection in infants (Rutenberg and Baek 2005; Stringer et al. 2007; Reynolds et al. 2008). A variety of behavioural and structural interventions that reduce HIV-related risk behaviours are of possible but uncertain utility, due to conflicting trial and study evidence (Gupta et al. 2008; Medley et al. 2009; Rotheram-Borus et al. 2009; Kennedy et al. 2010a, 2010b; Michielsen et al. 2010; Shepherd et al. 2010; Free et al. 2011; Johnson et al. 2011; Tan et al. 2012; Wariki et al. 2012).

Testing and linkage to care as a core strategy

The person who knows his or her own HIV serostatus is in a position to access HIV prevention or care services as they are provided in a given community; thus testing is a first gateway (Sanchez and Sullivan 2008). While people testing HIV seronegative may not change their risky behaviours, people testing HIV seropositive tend to reduce their sexual transmission risk behaviours significantly (Denison et al. 2008). People who do not know their own or their partners' serostatus are far less likely (range of 50–66 per cent) to use condoms. It is estimated that less than 20 per cent of adults in sub-Saharan Africa have been tested for HIV, yet the HPTN 043 NIMH Project ACCESS study demonstrated in a community RCT how community mobilization can increase testing

rates up to tenfold (Sweat et al. 2011). The best HIV testing access includes provider-initiated, routine or opt-out testing, and voluntary home-based HIV counselling and testing (HBCT) (Marum et al. 2012). HBCT may be cost-effective for population-level scale-up in generalized epidemics, despite its higher programmatic costs.

Once a person is tested for HIV, those testing positive must be linked to cART-based care. In the HPTN 052 trial, excellence in cART care and adherence reduced viral replication and reduced HIV transmission to sexual partners by 96 per cent, termed a 'game-changer' by the director of UNAIDS (Cohen et al. 2011). HIV-infected people with 350–550 CD4+ cells/microlitre were assigned randomly to receive ART either immediately (early therapy) or after a decline in the CD4 count to 250–350 cells/microlitre or the onset of HIV-1-related symptoms (delayed therapy). Given the success of TasP in HPTN 052 when people with high CD4+ cell counts were the target, the option of immediate treatment for all HIV-diagnosed people, regardless of immunological status, is ideal, if resources are available. Still, a combination of interventions is inherently needed to make TasP a reality in public health terms: HIV testing has to be brought to scale, effective linkage to care must be a key priority for primary care programmes, and high coverage and adherence to cART must be nurtured. WHO's estimate of a 23 per cent yearly ART attrition rate in Africa illustrates the tremendous challenge faced by the public health community in this regard (Renaud-Thery et al. 2011). It is plausible that a universal testing and treatment approach (regardless of CD4+ cell count) could reduce stigma in communities where testing is common and infection is simply treated in everyone, as with other infectious diseases or chronic disease conditions.

Given this need for expanded HIV testing, accessing the service, and willingness to adhere to the prevention modality (e.g. VMMC, future HIV vaccine or microbicide, cART regimen, consistent and correct condom use), behavioural co-interventions are essential. Prevention for positives to reduce risky behaviours with counselling focused on building motivation and developing skills is promising. Interventions based on sound behavioural theory, such as the Health Belief model, can help address mental health and substance use issues, with a focus on adherence. Condom use will continue to be emphasized as an adjunctive tool for HIV/STI risk reduction (Holmes 2004; Stoneburner and Low-Beer 2004). The biomathematics of combining methods for prevention are compelling, but intimidating at the same time; substantial coverage will be needed to succeed in bringing the basic reproductive rate to less than 1 thereby offering the potential prospect of eventual elimination of HIV as a public health problem (Andrews et al. 2012; Eaton et al. 2012; Wagner and Blower 2012).

Future directions

A new construct for viewing the global HIV pandemic through the prism of MSM risk has been proposed by Beyrer et al. (2011). Based on a systematic review of published and unpublished literature from 2000 to 2009, the authors selected 133 HIV prevalence studies from 50 countries to apply an algorithmic approach for categorization. Four scenarios for LMICs were suggested: (1) settings where MSM are the predominant contributor to HIV transmission; (2) settings where HIV transmission among MSM occurs in the context of epidemics driven by PWID; (3) settings where HIV transmission among MSM occurs in the context of

well-established HIV transmission among heterosexuals; and (4) settings where both sexual and parenteral modes contribute significantly to HIV transmission. Perhaps this paradigm can serve as a model of how to guide prevention strategies by reminding policymakers and HIV control workers as to what populations are the largest drivers of local transmission dynamics.

Among the major achievements in confronting the HIV pandemic have been the development and deployment of cART that can turn a previously fatal disease into a chronic, manageable one. However, lower-income nations have huge health services challenges that must be addressed for PEPFAR achievements to be expanded and sustained (Table 8.13.4). Even in the United States and Western Europe, there is a sense of HIV fatigue such that economic downturns from 2008 onwards seem to invite cuts in HIV programmes to satisfy fiscal exigencies. However, we know from the experiences of the past that failure to prevent HIV, or to treat it early once infection has occurred, will simply cost society more in the long run, given the high direct costs of illness and indirect costs of disability or death (Walensky et al. 2006; Schwartzlander et al. 2011). Prevention, including testing and early cART treatment, is a good societal and economic investment. Yet despite vast societal benefits (Walensky et al. 2006; Parham et al. 2010), HIV prevention and care are threatened in an era of fiscal constraint and global expenditure cuts in healthcare and prevention (Schneider and Garrett 2009; Holmes et al. 2012; Vermund et al. 2012).

Acknowledgements

We dedicate this chapter to our patients and friends who have died and who continue to struggle with HIV/AIDS.

Note

1. HIV/AIDS is a vast topic and within our space constraints, we have emphasized the public health aspects of this field. However, since treatment as prevention is a vital component of viral prevention, we also present a brief overview of HIV therapy.

Tuberculosis

David W. Dowdy, Richard E. Chaisson,
and Gavin J. Churchyard

Introduction: burden of tuberculosis disease

Tuberculosis (TB) has been ‘the Captain of all these men of death’ (Bunyan 1680) for centuries, and has probably killed more than 100 million people throughout history. Although the past 125 years have seen extraordinary scientific progress with respect to the disease, including identification of the organism by Koch, development of a vaccine by Calmette and Guérin, discovery of antibiotics active against the organism by Schatz, Waksman, and others, and many improvements in diagnostic methods, TB continues to exact a tremendous toll of suffering and death worldwide. An estimated 8.7 million people worldwide developed active TB in 2011, of whom 1.4 million died (World Health Organization (WHO) 2012), making *Mycobacterium tuberculosis* second only to HIV as the most deadly infectious agent in the world (WHO n.d.). TB remains the leading cause of death in people living with HIV; HIV-associated TB accounts for an estimated 13 per cent of all TB cases, and 30 per cent of all TB deaths (WHO 2012). Unlike HIV and malaria—which have seen declines of 15–25 per cent in the annual number of incident cases over the last decade—the size of the TB epidemic has remained nearly constant during this time, with the fall in incidence rates closely matched by the increase in size of the global population. As a result, the total burden of TB morbidity has been greater over the past decade than at any other time in human history.

Tremendous disparities exist in the burden of TB disease. Globally, TB is more highly concentrated in low- and middle-income countries, and within countries rates are almost always higher in the poor than the wealthy. Demographically, disease rates are highest in young adults and historically men have had higher disease rates than women, though this varies regionally (Connolly and Nunn 1996; WHO 2012). Over 80 per cent of TB cases occur in 22 high-burden countries; China and India alone account for 38 per cent of all TB cases (WHO 2011a). Rates of TB are affected by socioeconomic, environmental, and biological factors, with substantially higher rates in settings afflicted by poverty (Spence et al. 1993), conditions that promote transmission, such as crowded prisons, health facilities and informal settlements, high HIV prevalence (Chaisson and Martinson 2008), and other biological and social determinants (Lonnroth et al. 2009). As a result, TB incidence is nearly ten times higher in Africa (262 per 100,000/year), for example, than in the Americas (28 per 100,000/

year) (WHO 2012). Fig. 8.14.1 shows estimated TB incidence by country in 2011. The heterogeneity of TB burden underscores the importance of targeting interventions at the areas of greatest TB incidence (Dowdy et al. 2012).

Wealthy nations have seen large declines in the burden of TB, even before the advent of antibiotics. From the 1950s to the 1980s, the incidence of TB disease in the United States fell by about 8 per cent per year (Rieder et al. 1989). In the early 1980s, large reductions in funding for TB control programmes were imposed and coupled with an increase in HIV infections, homelessness, and incarceration led to a resurgence in TB cases and an epidemic of multidrug-resistant (MDR) TB from 1985 to 1992, which was then effectively contained by a massive infusion of funding for comprehensive strengthening of the TB control infrastructure. Ten years of intensive TB control efforts in Peru from 1991 to 2001, which focused on improved case detection and cure, resulted in an annual decline in incidence of nearly 6 per cent, with an estimated 70 per cent reduction in deaths from sputum smear-positive TB. Similarly, expansion of TB control efforts in China between 1990 and 2010 halved TB prevalence and reduced TB mortality in that country by an estimated 80 per cent (WHO 2011a). However, these successes in TB control are counterbalanced by failures. In Africa, the number of TB cases more than doubled between 1990 and 2005 (Chaisson and Martinson 2008); and estimated TB incidence in South Africa has tripled (WHO 2012). Approximately 25 per cent of all TB in China is now resistant to one of the two cornerstone drugs of TB treatment (isoniazid and rifampin), and 11 per cent are resistant to both (Zhao et al. 2012). Of the 22 high-burden countries, over half have not achieved any reduction in estimated TB incidence since 1990, and up to 30 per cent of people worldwide who develop active TB still never receive an appropriate diagnosis. Thus, while we have proven control strategies that can successfully control TB, these strategies have been only sporadically implemented.

Foundations of TB natural history and the public health response

Natural history of tuberculosis

The causative agent of TB is *Mycobacterium tuberculosis*, a slow-growing bacillus uniquely adapted to persistence in humans, who are the principal reservoir of the organism. *M. tuberculosis* is spread person to person via the airborne route, with untreated

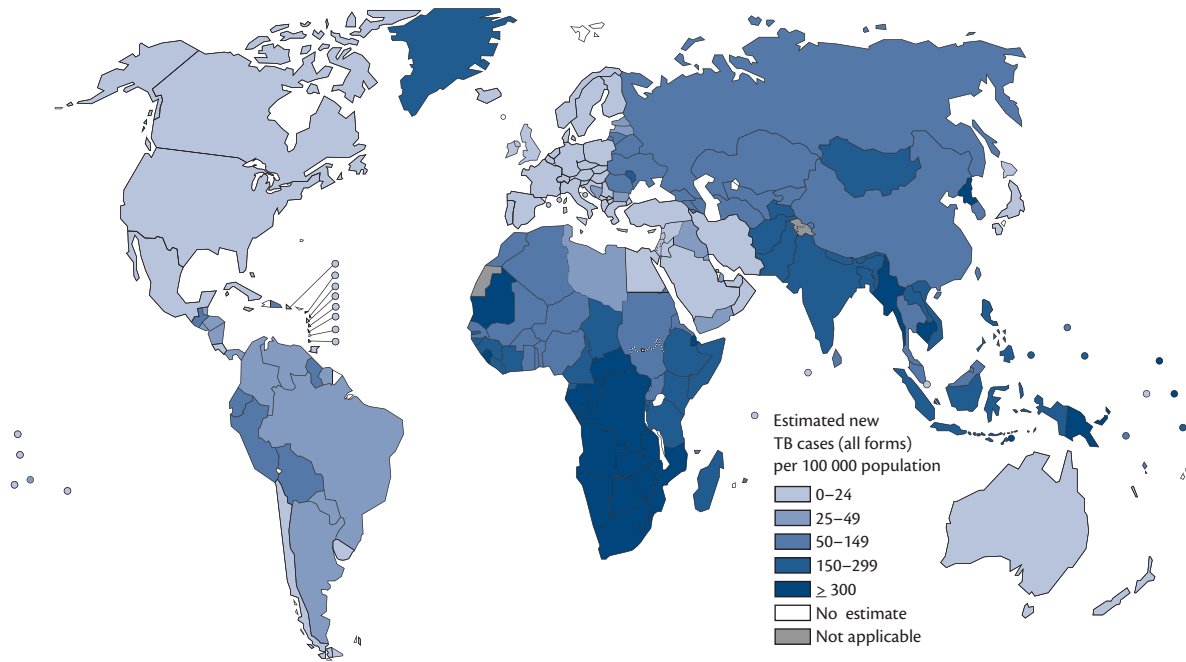

Fig. 8.14.1 Global TB incidence in 2011.

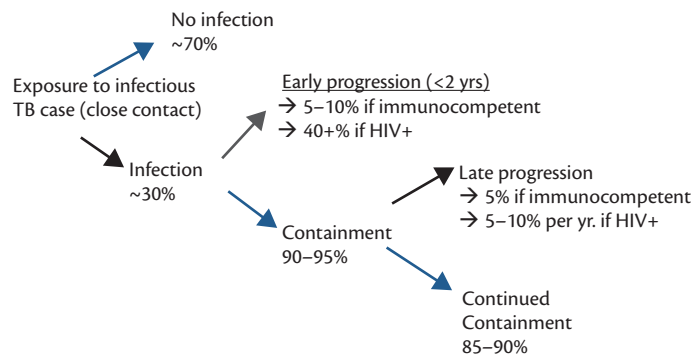

Fig. 8.14.2 Natural history of TB.

patients serving as the source. As shown in Fig. 8.14.2, the first step in the natural history of TB disease is infection with *M. tuberculosis* bacilli, which are suspended in tiny droplet nuclei expelled by infectious individuals, and are inhaled by those sharing the same air (van Leth 2008). Studies in household contacts of patients with infectious, untreated TB reveal that the majority of individuals escape infection, with only about one-third acquiring latent TB infection as measured by tuberculin skin test (TST) positivity (Fox et al. 2013).

Risk factors for becoming infected as a result of such exposure include the severity of illness in the index case, the closeness of contact, and the duration of exposure. Once an individual is infected with *M. tuberculosis*, symptomatic disease does not develop

immediately. For the majority of individuals, host defences, both from the innate and adaptive immune systems, contain the infection and prevent the onset of clinical disease. However, a small proportion of newly infected individuals will progress to clinical disease in the first several years ('primary progressive TB'), and among those who contain the initial infection, bacilli may later escape immune control sufficiently to cause symptomatic disease ('reactivation TB'). The greatest risk of disease is in the first year after infection, when 3-10 per cent of immunocompetent adults develop active TB (Vynnycky and Fine 1997), and the risk falls sharply thereafter, with a persistent small risk of reactivation, estimated at about 0.05 per cent per year in the United States, throughout life. The risk of progression to active TB at each point

in time after infection is dramatically increased by HIV infection and other forms of immunosuppression (e.g. high-dose steroids, cancer chemotherapy, tumour necrosis factor- α blockade, and poorly controlled diabetes).

Latent TB infection was previously perceived as a static state in which mycobacteria were dormant, and thus metabolically inactive and non-infectious. Now, latent TB is understood at the immunological level to comprise a spectrum of dynamic host-pathogen responses, some of which involve persistence of viable, metabolically active and potentially transmissible bacilli (Barry et al. 2009). Furthermore, population-based surveys have found that the majority of individuals with culture-confirmed prevalent TB are asymptomatic, some of whom may not progress to symptomatic disease if untreated (Corbett et al. 2007; Hoa et al. 2012). Thus, the classical distinction between 'latent' (i.e. asymptomatic, non-infectious) and 'active' (i.e. symptomatic, infectious) TB may not apply as rigidly as once thought.

Once symptomatic pulmonary TB has developed in an immunocompetent adult, it is a progressive and often fatal disease if left untreated. Modern estimates are that the median duration of untreated TB disease in HIV-uninfected adults may range from 3 months to 3 years, with a case-fatality ratio of approximately 50 per cent if untreated (Tiemersma et al. 2011). Even in the age of modern diagnosis and treatment, it is estimated that the global prevalence of undiagnosed active TB is greater than the annual incidence. Undiagnosed, infectious TB therefore remains the driving force that sustains modern epidemics.

Individuals who have been infected with TB in the past may be reinfected and subsequently progress to active TB. Latent TB infection may provide partial protection against subsequent disease due to reinfection, with an up to 80 per cent lower likelihood of active disease following re-exposure (Andrews et al. 2012). Nevertheless, reinfection events may account for the majority of TB cases in areas of hyperendemic infection, possibly due to a larger cumulative inoculum of infection or differences in pathogen virulence after multiple exposures. Thus, unlike many other infectious diseases with prolonged infectious periods (e.g. HIV, hepatitis B), reinfection is a central consideration to the natural history, epidemiology, and control of tuberculosis.

Paediatric TB

Children 15 years old and younger account for only 2 per cent of TB cases notified to the WHO, although official estimates are that 6 per cent of TB cases occur in children (WHO 2012), and community-based surveillance data suggest that children account for 10–20 per cent of all incident TB cases in high-burden regions (Marais et al. 2006). This disparity reflects the difficulty of diagnosing TB in children with existing tools. The clinical manifestations of TB in children—as in adults with HIV infection—are often non-specific and protean (e.g. fevers and weight loss). The sensitivity of sputum smear microscopy in young children—many of whom have extrapulmonary disease—is less than 10 per cent. Other techniques, such as gastric lavage, have variable accuracy and are logistically challenging, requiring invasive testing. As a result, effective diagnosis of TB in children generally requires a combination of multiple tests, making the process expensive and

difficult to standardize. Many children are treated empirically, and many more die of TB while awaiting a diagnosis (Swaminathan and Rekha 2010). In low-incidence settings TB is mostly seen in adults, but in areas of high TB transmission, paediatric TB is commonplace. Children under 5 have a much higher per-capita TB incidence rate than adults, and in immunocompetent infants, the risk of developing lethal disseminated forms of TB (miliary TB and meningitis) after primary infection is as high as 10 per cent. Among children with HIV infection, the risk of TB progression and mortality is even greater. In autopsies of Zambian children dying of respiratory illness, TB was the second leading cause of death after bacterial pneumonia, even in the absence of HIV (Chintu et al. 2002).

Although adolescents often develop TB that is similar in presentation to that of adults, most young children with TB are relatively less infectious. Infants—who often develop severe TB manifestations relatively soon after infection—often serve as 'sentinels' of household transmission. Therefore, public health approaches to prevent paediatric TB focus on mitigating the effects of transmission from adult cases in the household rather than preventing TB transmission from children to others. *Bacillus Calmette–Guérin* (BCG) immunization is estimated to achieve 75 per cent efficacy in preventing disseminated forms of TB in children (WHO 2006), but is contraindicated in HIV-infected children because of the possibility of disseminated BCG disease. This represents an ongoing dilemma for national TB programmes as HIV-infected children are at greatest risk of TB. WHO also recommends that all children under 5 years old who come into contact with a smear-positive case be screened for TB infection and offered isoniazid preventive therapy after ruling out active TB (WHO 2006). This recommendation is also difficult to follow, owing to the logistical challenges of tracing household contacts for all TB cases, and of excluding active TB in young children given the limitations of existing diagnostic tools.

Risk factors for acquiring and developing tuberculosis

An individual's risk of becoming infected and developing active TB has long been understood to be a function of demographic (e.g. age, sex) and socioeconomic (e.g. poverty, housing density) factors. Because of its airborne route of transmission, TB has always affected a broad cross-section of society, but has disproportionately afflicted the poor and those living in cities. The urban squalor of the nineteenth century was associated with TB in literature, opera, and art, but strong associations between poverty and TB are still present in the twenty-first century. As shown in Fig. 8.14.3, per-capita gross domestic product and relative wealth are associated with rates of TB at the country and individual level. Many factors can modulate the impact of poverty on TB risk, including nutritional status, housing density, ventilation, and access to health services. In recent years, it is increasingly understood that biomedical co-morbidities, notably HIV infection, smoking, and diabetes mellitus, are also key drivers of the global TB epidemic. The relative proportions of TB disease attributable to specific risk factors in different epidemiological situations are being more accurately quantified.

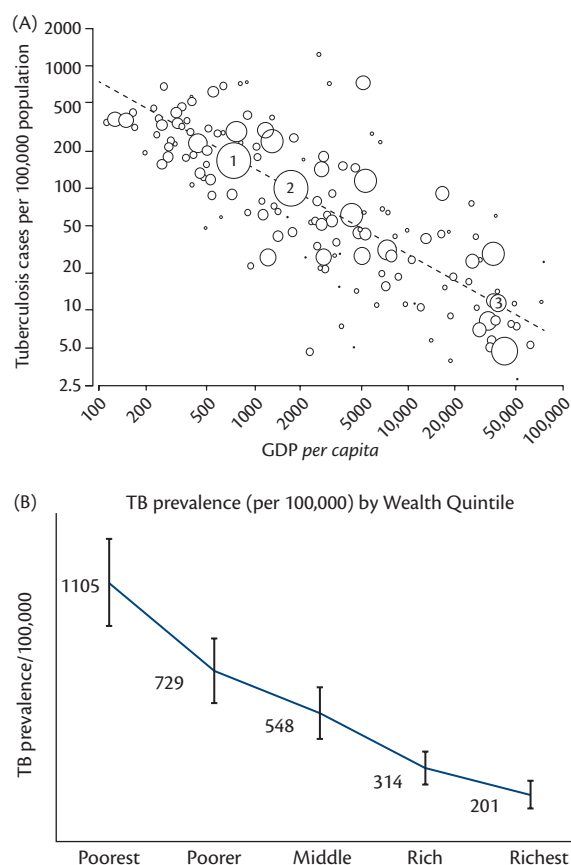

Fig. 8.14.3 Association between poverty and tuberculosis. (A) Reported tuberculosis incidence by per capita gross domestic product in 2004 (Janssens and Rieder 2008). (B) Self-reported tuberculosis prevalence in ~200,000 people in India by wealth quintile in 2008 (Oxlade and Murray 2012).

HIV infection

HIV infection profoundly alters cell-mediated immunity, the key to containment of *M. tuberculosis* infection. Individuals with HIV have a greatly increased risk of progressing from TB infection to disease. In adults with latent TB infection who acquire HIV, the risk of developing active disease doubles within a year and continually increases as cellular immunodeficiency worsens, with rates of 5 per cent to 15 per cent per year in advanced HIV disease. In individuals with HIV who become infected with *M. tuberculosis*, progression to active TB occurs rapidly, with up to 40 per cent developing clinical illness within 3 months of infection. HIV-infected individuals with successfully treated TB can be re-infected and experience high rates of disease when this occurs. Thus, in areas with a high burden of both TB and HIV infections, the co-epidemic is a function of reactivation of latent

TB infection, primary infection with rapid disease progression, and re-infection.

Both low CD4 cell count and high HIV plasma viral load are associated with risk of TB in co-infected individuals. Other predictors of TB in people with HIV include positive TSTs or interferon-gamma release assays, anaemia, elevated C-reactive protein and low body mass index. Treatment of HIV infection with antiretroviral therapy substantially lowers the risk of TB, with between 50 and 80 per cent reductions in incidence rates depending on the CD4 cell count at which treatment is started. Use of isoniazid preventive therapy also reduces risk, and the combination of both antiretroviral therapy and isoniazid preventive therapy has additive effects. Nonetheless, even with use of antiretroviral therapy and isoniazid preventive therapy, the risk of TB in people with HIV remains significantly elevated compared to HIV-negative people.

The HIV epidemic has transformed the epidemiology of TB in the last 25 years, particularly in sub-Saharan Africa. HIV is the strongest commonly encountered risk factor for TB, increasing the risk of developing active TB by a factor of 14 (in high-incidence areas) (WHO 2012) to 60 (in low-incidence ones) (Corbett et al. 2003). HIV co-infection also shortens the duration of TB disease (from symptom onset to death) from years to months (Corbett et al. 2004). TB accounts for one-quarter of HIV deaths worldwide (WHO 2011a). In eight countries of southern Africa, more than half of all TB cases occur in people living with HIV, and in South Africa, the country-wide incidence of TB is over seven times the global average. Primarily as a result of the increasing prevalence of HIV infection, the incidence of TB in Africa more than doubled between 1990 and 2005, at a time when TB incidence was stable or declining in every other region of the world (except Eastern Europe) (Chaisson and Martinson 2008).

The unique characteristics of HIV-associated TB demand a tailored public health response. In areas of high HIV prevalence, the dramatic increase in TB rates over the past 25 years has overwhelmed existing TB control structures. Furthermore, TB is more difficult to diagnose and treat in the setting of HIV infection. Extrapulmonary TB, disseminated TB and negative sputum smear results are all more commonly seen in HIV infected individuals. Whereas HIV-negative individuals with smear-negative TB are at relatively low risk of death, TB is highly lethal in the setting of HIV regardless of sputum smear status. TB diagnostic strategies based on sputum smear alone are therefore destined to fail for people with HIV infection. It is now widely accepted that early initiation of antiretroviral therapy (ART) in people with HIV-associated TB can save lives (Abdool Karim et al. 2011), but TB medications (especially rifampin) interact with key antiretroviral drugs (especially nevirapine and protease inhibitors). Up to one-third of individuals who start therapy for TB and HIV concomitantly will develop symptoms of the immune reconstitution inflammatory syndrome (IRIS) (Lawn et al. 2007), but integrated TB-HIV treatment can improve survival in co-infected patients (Abdool Karim et al. 2011). Not only does HIV impair diagnosis of TB using traditional tools, but it complicates TB treatment decisions as well.

Smoking

Observational studies have suggested for more than a decade that smoking is a major risk factor for TB mortality; in 2003, a study of 43,000 adult male deaths in India suggested that over half the TB deaths could be attributed to smoking (Gajalakshmi et al. 2003). Another large study of elderly individuals in Hong Kong found that smoking increased the risk of incident pulmonary TB nearly threefold (Leung et al. 2004). A systematic review confirmed an increased risk of detectable latent TB infection, active TB disease, and TB mortality among smokers, as well as those exposed to passive smoke and indoor air pollution (Lin et al. 2007). Smoking may also be associated with an increased risk of relapse after successful cure. An epidemiological model has suggested that tobacco smoke might increase the number of TB deaths by 66 per cent (40 million deaths) by 2050, relative to the theoretical scenario of no smoking (Basu et al. 2011).

Diabetes

In the pre-insulin era, TB caused up to 50 per cent of deaths in people with diabetes. More recent observational studies suggest that diabetes increases the risk of incident TB by a factor of three (Jeon and Murray 2008). Like smoking, diabetes may also have a negative impact on TB treatment outcomes, prolonging the time to culture conversion after initiation of treatment and increasing the risk of failure and death (Dooley and Chaisson 2009). The prevalence of diabetes is projected to rise by over two-thirds in the developing world from 2010 to 2030 due primarily to population growth, ageing, and lifestyle changes including diet and obesity, making sustained reductions in global TB incidence increasingly difficult to achieve.

Silicosis

The risk of TB is greatly increased in silicosis, which develops following silica dust exposure among granite workers or gold miners (American Thoracic Society Committee of the Scientific Assembly on Environmental and Occupational Health 1997). Silicotics have an increased risk of death from TB, particularly in countries where TB is hyperendemic. In the pre-HIV era in South Africa, the risk of TB was 2.7-fold greater in gold miners compared to non-miners, with the greatest risk among those with advanced (grade 3) silicosis (Cowie 1994). Silicosis also speeds the progression of TB disease, reducing the duration of undiagnosed active TB by about 80 per cent in miners with versus without silicosis (Corbett et al. 2000). The silicosis-related TB epidemic among miners has been further exacerbated by HIV. Despite intensive control efforts such as annual screening X-rays, TB incidence in South African mines routinely exceeds 1000 per 100,000/year. A cluster randomized trial of mass screening and treatment for both active and latent TB among 80,000 gold miners did not reduce TB incidence at a community level despite reducing the risk of TB by 58 per cent while individual miners were taking (but not after stopping) isoniazid preventive therapy (Churchyard et al. 2014; Fielding et al. 2012). Reducing TB transmission among silica exposed miners through combined strategies including early diagnosis and treatment, improved dust control, expanded use of antiretroviral therapy and continuous isoniazid preventive therapy is required.

Populations in congregate living settings

Prisoners

Globally, prisoners are at increased risk of TB (Baussano et al. 2010). Prisons are often characterized by overcrowding, poor ventilation, malnutrition, stress, vitamin D deficiency, and poor medical and public health programmes (Tuberculosis Coalition for Technical Assistance and International Committee of the Red Cross 2009). Prisons therefore take individuals with high epidemiological risk of active TB and expose them to conditions conducive to TB transmission (Baussano et al. 2010), and may act as a reservoir of TB with transmission to the general community. Spread of drug-resistant TB in prisons has also been described and is thought to be a major driver of the MDR-TB epidemic in the former Soviet Union. TB control in prisons can be strengthened by improving living conditions, ventilation, nutrition, and infection control. After incarceration, prisoners with untreated or ineffectively treated TB will continue to transmit TB, thus strengthening TB control in prisons benefits not only prisoners and staff but also communities.

Migrants and socially marginalized populations

As TB has declined in industrialized countries, the proportion of TB cases that are foreign-born has increased and now accounts for the majority of incident TB in many settings (Cain et al. 2008). Migrants from high TB burden settings may affect TB incidence in both high- and low-income regions; migration of southern African miners to and from their communities to South African mines is thought to have contributed to the spread of TB, including drug-resistant TB, within the Southern Africa region. Migrant populations may be at increased risk of TB due to poor nutrition, overcrowding, and poor access to healthcare; providing quality TB treatment and care in this environment is often challenging. In low-burden settings, socially marginalized populations, including homeless individuals, injecting drug users, and previously incarcerated individuals, are at increased risk of poor treatment outcomes and account for a substantial burden of TB disease. Migrant and marginalized persons require access to quality TB screening, treatment and prevention services to reduce their risk of TB and potentially interrupt transmission to the general community.

Population attributable fraction

As our understanding of the impact of various risk factors on TB incidence and mortality has deepened, quantitative projections of attributable burden have become feasible. One method for estimating the population-level burden associated with various risk factors is to calculate the population attributable fraction (PAF), defined as the proportional reduction in TB incidence that could be achieved by completely eliminating a risk factor entirely, assuming that observed epidemiological associations are completely causal. The PAF typically overestimates the fraction of disease causally resulting from a given risk factor, but it provides a useful metric for comparing the population-level burden of TB associated with diverse determinants. Such projections have led to important conclusions for shaping the future of TB control efforts.

In many locations, the strongest determinant of TB incidence is the overall economic status of a population (discussed earlier) (Dye et al. 2009). Thus, general improvement of economic conditions is likely to have substantial positive impact on TB control. Additionally, there exists a striking geographic heterogeneity in

the drivers of TB epidemics worldwide. For example, HIV is associated with more than 50 per cent of TB in southern Africa, but only 1 per cent in China and 5 per cent in India, the two countries with the greatest burden of TB. Similarly, elimination of all tobacco smoking might reduce TB incidence by 20 per cent in Indonesia but only 4 per cent in Nigeria. Other settings in which specific determinants are driving country-wide epidemics of TB include alcohol abuse (PAF 35 per cent) and smoking (PAF 29 per cent) in the Russian Federation, smoking (PAF 21 per cent) in China, and undernutrition in Africa (PAF > 40 per cent in multiple countries). While HIV continues to drive the TB epidemic in sub-Saharan Africa, it is associated with only 11 per cent of TB incidence worldwide. Globally, elimination of undernutrition, smoking, and indoor air pollution would have greater impact on TB incidence than elimination of HIV, and interventions to curb alcohol misuse and diabetes would also generate substantial reductions in incidence. As our knowledge of TB risk-factor epidemiology continues to grow, it will become possible to expand these projections to TB progression, treatment outcomes, and mortality as well.

In addition to the PAF approach, epidemiological (transmission) modelling provides further insight into the potential impact of TB control interventions, by projecting the effects of those interventions on future TB transmission. For example, HIV may have greater impact on TB incidence and mortality than on transmission, since HIV-associated TB is often shorter in duration and may be less infectious. By contrast, smoking may increase TB transmission by leading to longer diagnostic delays—and thus prolonged transmission time—as cough is not initially recognized by the patient to be abnormal. Ultimately, the impact of a given epidemiological risk factor on the future burden of TB is a combination of its strength of causal association (e.g. relative risk), prevalence in the general population, and impact on transmission. Understanding each of these elements in a given epidemiological context is essential for crafting public health responses to TB that are geographically tailored and appropriate to the population-level burden of TB caused by specific determinants of disease.

Evolution of TB control

The historical cornerstones of TB control have been the detection and treatment of cases with antituberculosis chemotherapy and prevention of disease with a vaccine. In the century before the advent of antibiotics for TB, treatment consisted of bed rest, fresh air, and nutrition; these were sometimes provided in sanatoria, isolated bucolic or alpine facilities for those able to afford them. The development of antimicrobial agents, such as streptomycin in 1943, permanently altered the management of the disease; ambulatory chemotherapy for TB became widespread and sanatoria around the world closed. Strategies for finding cases in the community through mass radiography or symptom screening were employed for a number of years, referring cases found into treatment programmes. From 1974 to 1991, the WHO recommended that TB control policies focus on passive detection of cases, relying on symptomatic individuals presenting to health services for diagnosis and treatment.

Coupled with passive case detection and treatment was the widespread use of a vaccine against TB. BCG is a live, attenuated strain of *M. bovis* developed by Calmette and Guérin at the Pasteur Institute in Paris and first used in the 1920s. Early studies

of the vaccine found it highly efficacious, reducing paediatric forms of TB by as much as 83 per cent (Colditz et al. 1995), but trials over the past 30 years have not shown any consistent benefit for preventing adult TB. Currently there are multiple strains of BCG used around the world, with notable genomic differences, and the effectiveness of BCG is heterogeneous across populations. One explanation for the variable effects of BCG vaccines over time and geography is further attenuation of the immunogenicity of vaccine strains with further laboratory passage (Behr et al. 1999). Despite this inconsistent evidence of effectiveness, BCG is given at birth to the vast majority of infants around the world, with booster vaccinations given in many countries (Zwerling et al. 2011). This widespread uptake has not blunted global TB incidence or mortality.

Progression from latent TB infection to active disease can also be prevented by administration of the anti-TB drug isoniazid, with an efficacy of at least 65 per cent (Comstock 1999). Since 1998, isoniazid preventive therapy has been endorsed for people with HIV infection, and more recent guidelines have increasingly emphasized its use. Uptake of isoniazid preventive therapy, however, has played little role in global TB control for many years.

In the early 1990s, the WHO launched a new strategy for global TB control called directly observed therapy, short-course (DOTS). This strategy was supported by epidemiological models suggesting that existing tools, used appropriately, could control and eventually eliminate the disease (Styblo and Bumgarner 1991). DOTS consists of five elements: political commitment, registration and monitoring of cases, assuring a reliable supply of anti-TB drugs, case detection with bacteriology, and standardized treatment with supervision of at least the initial phase of therapy. DOTS was scaled-up from 1995 to 2010, with most countries adopting it as a TB control strategy. It has been credited with saving millions of lives since its introduction, and remains a key element of the current WHO Stop TB Strategy (2011). Although it is now widely recognized that scaling up DOTS alone will not achieve global TB control, DOTS remains one of the most successfully deployed comprehensive public health responses to a single disease.

A key historical target under DOTS was to successfully diagnose and notify 70 per cent of all cases of smear-positive TB (Dye et al. 1998). However, the sensitivity of sputum smear microscopy is relatively low, especially in children, people living with HIV and people with extrapulmonary TB. As a result, the potential for achieving worldwide TB control using sputum smear microscopy as the sole diagnostic test is limited and unrealistic. Nevertheless, rapid and accurate diagnosis of individuals with smear-positive TB remains an essential component of any TB control strategy.

Equally important to accurate and rapid diagnosis is standardized treatment. The current first-line treatment regimen for new, drug-susceptible pulmonary TB entails at least 6 months of therapy, including four drugs—isoniazid, rifampin, pyrazinamide, and ethambutol (Table 8.14.1)—during the intensive phase (usually 2 months) and two drugs—isoniazid and rifampin—during the subsequent continuation phase (usually 4 months) (WHO 2010a). For individuals without drug-resistant TB, successful completion of this course of therapy cures virtually all patients; only 2–3 per cent will relapse over long-term follow-up (Menzies et al. 2009). Unfortunately, standardized 6-month therapy also has important limitations. The treatment success rate in people who receive care outside the public health system is markedly lower

Table 8.14.1 Traditional and updated categorization of drugs for TB

Group 1: first-line oral drugs	Isoniazid
	Rifamycins: rifampin, rifabutin and rifapentine
	Ethambutol
	Pyrazinamide
Group 2: injectable drugs	Streptomycin
	Kanamycin
	Amikacin
	Capreomycin
Group 3: fluoroquinolones	Moxifloxacin
	Levofloxacin
	Ofloxacin
Group 4: oral bacteriostatic second line drugs	Ethionamide
	Prothionamide
	Cycloserine/terizidone
	Para-aminosalicylic acid
Group 5: drugs of unclear efficacy	Clofazimine
	Clarithromycin
	Amoxicillin-clavulanate
	Linezolid
	Thiocetazone
^a Group 6: new agents with novel mechanisms of action	Bedaquiline
	Delamanid
	Linezolid/sutezolid and other oxazolidinones
	PA-824

^a Group 6 has been added by the authors.

than among those treated under DOTS, existing first-line drugs have substantial toxicity and interactions with other medications (particularly antiretrovirals) (Yee et al. 2003), and an estimated 11 per cent of new TB cases are now resistant to at least one first-line drug (Wright et al. 2009).

To address limitations in the initial DOTS policy, the WHO updated its Global Plan to Stop TB in 2006 (Stop TB Partnership 2006) and again in 2011 with specific emphasis on addressing HIV-related TB and MDR-TB, strengthening health systems, engaging the private sector and empowering communities to contribute to TB control (Stop TB Partnership 2011a). In addition, the WHO strongly emphasized the importance of research into new methods to improve TB control. The revised Global Plan also included detailed budget projections and estimated that meeting the Millennium Development Goals (MDGs) for TB would cost \$56 billion between 2006 and 2015, but noted that only \$23 billion was available.

Implementation of the WHO DOTS/Stop TB strategy has resulted in substantial achievements in TB care and control globally. The treatment success rate among all new TB cases worldwide currently stands at 85 per cent (87 per cent for smear-positive pulmonary TB), and an estimated 20 million lives have been saved since DOTS was begun. However, in Africa and Eastern Europe,

TB incidence is only now returning to the 1990 baseline. TB prevalence has declined by 36 per cent globally since 1990, but current projections suggest that the target for halving TB prevalence will not be met globally.

To improve control of TB in the setting of high HIV prevalence, the WHO endorsed a strategy known as the '3 I's' for HIV-associated TB: *intensified* case finding, *isoniazid* preventive therapy, and *infection* control. These three elements underscore three important aspects of an appropriate public health response for HIV-associated TB. Intensified case finding is aimed at identifying HIV-infected individuals with active TB before they would be diagnosed under passive case finding, in order to reduce mortality and transmission. Isoniazid preventive therapy reduces the risk of TB in people with HIV substantially, particularly while they are taking the drug, and the combination of IPT and antiretroviral therapy can reduce TB risk by up to 90 per cent. Furthermore, people living with HIV are more likely to visit health centres and be hospitalized, where mixing of patients exquisitely susceptible to disease with others transmitting infection results in high rates of TB disease. Health centres and hospitals are frequent sites of TB outbreaks, including outbreaks of highly drug-resistant TB, among people living with HIV—often with highly fatal consequences. Infection control is therefore particularly important for prevention of TB transmission among people living with HIV.

Drug-resistant TB

Resistance to anti-TB drugs has existed since the first use of streptomycin; a large proportion of patients treated with streptomycin monotherapy in the first controlled trial of TB chemotherapy developed resistant infections (Medical Research Council 1948). Today, resistance to isoniazid is widespread and resistance to both isoniazid and rifampin, defined as MDR-TB, is increasingly prevalent.

Drug-resistant TB arises from rare, spontaneous mutations in the *M. tuberculosis* genome that renders the bacterium resistant to the action of the drug. In patients with active TB disease, a very small number of the organisms present in the body will harbour mutations to any one drug. In latent TB infection, where the number of viable organisms is even smaller and rates of division lower, the probability of even a single spontaneous drug resistance mutation is very low. The probability of simultaneous mutations to multiple drugs is small (e.g. $10^{-9} \times 10^{-9}$). Thus, combination therapy with several anti-TB drugs is effective even against a population of bacilli with small numbers of monoresistant organisms. However, improper treatment (e.g. sequential monotherapy) allows resistance to emerge with much greater probability. This process, referred to as *acquired drug resistance*, has historically been the most common means by which drug-resistant TB occurs. However, once acquired, drug-resistant TB can be transmitted to others, a situation referred to as *primary drug resistance*. In recent years, the proportion of drug resistant TB due to primary resistance has increased, but previously treated individuals are still more likely to have MDR-TB (Dalton et al. 2012).

MDR-TB is difficult to diagnose and requires treatment with second-line agents, which are more toxic, more expensive, and less efficacious. Treatment for MDR-TB typically involves five agents, a 24-month treatment course (of which 8 months require an injectable agent), and treatment costs that are at least ten times higher than for drug-susceptible TB (WHO 2010b, 2011b). Even

with optimal therapy, however, fewer than 70 per cent of patients with MDR-TB are cured with current regimens (Orenstein et al. 2009). The Global Project on Anti-Tuberculosis Drug Resistance Surveillance reports that the global prevalence of MDR-TB in 2006 and 2010 was approximately 5 per cent (3 per cent in new cases and 20 per cent in previously treated cases) (Wright et al. 2009; Zignol et al. 2012). However, these data are notable for their lack of completeness (less than 2 per cent of TB patients without a prior treatment history are currently tested for drug susceptibility) and their heterogeneity. MDR-TB is a particular challenge in the countries of the former Soviet Union, where partial treatment of TB in prisons has played a key role in amplifying drug resistance. Almost 50 per cent of MDR-TB cases occur in India and China; a national survey estimated that China has over 100,000 incident cases of MDR-TB per year, the majority of which now result from primary transmission rather than acquired resistance (Zhao et al. 2012). In countries that have mounted an aggressive response to the threat of MDR-TB, notably the United States, which experienced a surge in MDR-TB prevalence in the early 1990s, the prevalence of TB drug resistance has declined (Wright et al. 2009). However, in the Tomsk Oblast of Russia, the prevalence of MDR-TB among all cases increased from 18 per cent to 28 per cent in a span of just two years (2003–2005) (Wright et al. 2009) highlighting the explosive potential of MDR-TB in the setting of insufficient public health vigilance and funding.

An effective public health response to the threat of MDR-TB involves both diagnosis and treatment (WHO 2011b). First, it is essential to scale up laboratory capacity for drug susceptibility testing (DST). As of 2008, in 27 high-MDR-TB countries, only nine had more than two quality-assured labs capable of testing for drug resistance (WHO 2011b). Second, patients with MDR-TB must have access to uninterrupted and high-quality second-line drugs. The Green Light Committee (GLC) is an international initiative to supply such drugs at a reduced price and has approved treatment for MDR-TB patients in over 70 countries; however, in 2008, it was estimated that only 1 per cent of all incident cases received second-line treatment through the GLC (WHO 2011b). Financing the MDR-TB response is particularly challenging; the cost of MDR-TB treatment alone exceeds per-capita gross national income in all 27 high-MDR countries, and many countries devote over half of their national TB control budgets to treating the less than 5 per cent of cases with MDR-TB.

The number of drugs to which TB is resistant is increasing, raising the spectre of TB that is completely untreatable. In 2006, the first cases of extensively drug-resistant (XDR)-TB, defined as MDR-TB plus resistance to a fluoroquinolone and at least one of three second-line injectable drugs, were reported as part of a nosocomial outbreak in KwaZulu-Natal, South Africa (Gandhi et al. 2006). Case-fatality in the HIV-fuelled outbreak was 98 per cent, with death occurring in a median 16 days after diagnosis. XDR-TB has subsequently been identified by routine surveillance in over 20 countries, in every region of the world (Zignol et al. 2012). In 2012, a case series highlighted four TB patients with documented resistance to all first- and second-line drugs with susceptibility tests available (Udwadia et al. 2012). This situation highlights the need to develop new drugs in the anti-TB armamentarium, but more importantly, effective public health approaches to diagnosing and

treating drug-resistant TB in order to curb the emergence of such widely-resistant, potentially untreatable, organisms.

Progress in the public health response to tuberculosis

TB case finding

If TB prevalence and mortality are to be halved in a period during which TB incidence is declining by about 2 per cent per year globally, the duration of disease must be shortened, and people with active TB must be diagnosed before it is too late to avert death. Thus, passive case finding—‘detecting active TB disease among symptomatic patients who present to medical services for diagnosis of symptoms’—must be augmented by more active methods (Ayles et al. 2013). Population-based TB prevalence surveys have shown that many individuals with prevalent TB are asymptomatic. Many ‘asymptomatic’ individuals may actually have mild symptoms, but neither patients nor clinicians regularly recognize these as indicative of TB. Thus, whereas classic symptom screening and sputum smear microscopy may be effective clinical tools for diagnosis of advanced TB disease (in the absence of HIV infection), they are far less useful as public health tools for reducing the infectious burden in the community through detection of prevalent infectious cases. The ‘typical’ findings of at least one of cough, fever, weight loss, or night sweats has a positive predictive value of less than 25 per cent in HIV-infected populations, though negative predictive value is generally over 90 per cent.

Without actively finding prevalent cases in the community, we cannot hope to substantially reduce the burden of TB transmission—as the majority of transmission likely occurs before individuals with active TB ever seek care. But prevalent TB is a rare disease at the population level. In a typical high-burden setting, 500 community members would need to be screened—at an estimated cost of at least US\$10 per person—to identify one person with active TB. To have a 50 per cent chance of detecting that case, a method with higher sensitivity than symptom screen and sputum smear would need to be used. The most realistic method at present would be to use chest X-ray—with a sensitivity (for any abnormality) of greater than 90 per cent—as an initial screen, with culture or other high-sensitivity bacteriologic assay for confirmation. However, in most settings, the cost of this community-based case finding strategy at current prices would exceed \$10,000 per case detected. Several studies in Africa have suggested that household- or community-based active case finding may reduce TB prevalence by up to 20–40 per cent over a period of a few years, but one trial (ZAMSTAR) found that an untargeted enhanced case-finding strategy had little effect on community-wide incidence or prevalence (Ayles et al. 2013). The failure to demonstrate community-level benefit of active TB screening reflects the immense logistical challenges in finding and treating early cases at a community level, not the inability of active case finding to contribute to TB control.

This reality—that the majority of TB transmission in the community is fuelled by cases that are rare on the population level and therefore resource-intensive to detect—has deepened an understanding that innovative, targeted approaches to active TB case finding are an essential component of the public health response to TB. These approaches must be targeted to the specific epidemiological situation into which they are deployed,

with the aim of detecting prevalent cases more efficiently than in the community-based screening scenarios studied. Additional strategies include screening of high-risk individuals such as HIV-infected individuals, diabetics, and those in congregate settings such as prisons and mines. These initiatives provide reason for optimism that active case-finding strategies can be developed which directly reduce TB prevalence and mortality without overwhelming available TB control infrastructure and budgets.

Management of HIV-associated TB

Countries with HIV-driven TB epidemics must confront both the challenge and the opportunity afforded by the ubiquity of HIV infection among individuals with active TB. On the patient level, concomitant diagnosis, linkage to care, and effective treatment of both TB and HIV requires numerous steps to be taken and systems to be navigated. On a clinical level, the benefits of combined HIV-TB services are clear. Antiretroviral therapy (ART) reduces the risk of developing active TB by about two-thirds; initiating ART at the time of TB diagnosis (versus 8–12 weeks later) reduces mortality by up to 40 per cent in patients with severe immune compromise (Havir et al. 2011); and dual testing for HIV and TB is an efficient method to detect and treat prevalent TB in the community. Integration of TB and HIV services has therefore been recommended for all areas with high HIV prevalence. However, successful models for such integration remain relatively uncommon. Challenges that confront integrated delivery of care for TB and HIV include clinical concerns (e.g. drug interactions, immune reconstitution), administrative barriers (e.g. different funding streams and organizational structures), and cultural differences (e.g. directly-observed therapy in TB versus patient empowerment for self-administered therapy in HIV). Nevertheless, a number of models demonstrating how HIV and TB delivery systems can be successfully integrated in high-burden settings have been published (Gandhi et al. 2009). From 2004 to 2011, the percentage of people with *diagnosed* incident TB in Africa who were tested for HIV rose from 4 per cent to 69 per cent, and the number of HIV-infected individuals screened for TB rose from under 100,000 to 3.2 million (WHO 2011a).

Dramatic progress has been made with respect to delivery of ART and isoniazid preventive therapy. In the decade from 2002 to 2011, global access to ART among people in need rose essentially from 0 per cent to 50 per cent, suggesting that the goal of universal access is attainable in a short period of time. Although ART dramatically reduces the risk of developing TB, it is currently initiated late in the HIV disease course, such that much of its potential for TB prevention is untapped. Furthermore, ART also substantially extends life expectancy while not reducing TB incidence to levels seen by HIV-uninfected people; thus, late ART may even have the paradoxical effect of increasing TB incidence at the population level. It is unlikely that ART alone, as currently delivered, will effectively turn the tide of TB in southern Africa (Lawn et al. 2011).

Attention is being paid to early initiation of ART, a so-called ‘test and treat’ strategy of HIV control. One admittedly optimistic epidemiological model suggests that, if ART were initiated within 1 year of HIV seroconversion among all individuals in nine African countries, HIV-associated TB incidence could be reduced by 98 per cent by 2050 (Williams et al. 2010). While such a strategy would be impossibly resource-intensive on a global scale under

current financial conditions, it bears mention as a potential public health approach against both HIV and TB as HIV drug prices fall and less-toxic ART regimens are developed. Also of note, the ‘test and treat’ paradigm has recently been applied to TB control as well, emphasizing the importance of treating individuals with active TB on the same day that they are tested (Davis et al. 2012).

Isoniazid preventive therapy (IPT) for people living with HIV is recommended as part of the WHO ‘3 I’s’ approach. Uptake has been poor, with only 12,000 HIV-infected people worldwide registered as taking IPT by 2004. By 2010, this number had risen to 180,000, due largely to South Africa increasing its delivery of IPT from 24,000 to 124,000 people between 2009 and 2010 alone. While South Africa has demonstrated the feasibility of rapid scale-up, IPT uptake in other countries remains slow. A series of recent trials has broadened our understanding of the community-level impact of IPT among people living with HIV, and is likely to influence the global public health approach to IPT delivery in coming years. In Botswana, IPT for 36 months reduced TB incidence by over 40 per cent compared to 6 months of IPT; the effectiveness of the 6-month regimen began to wane within 6 months of completion (Samandari et al. 2011). In Brazil, where rates of ongoing TB transmission are substantially lower, a 6-month course of IPT delivered only to TST-positive individuals within HIV clinics reduced overall adjusted TB incidence rates by 27 per cent at the clinic level and by over 50 per cent among those who remained in consistent clinical care (Durovni et al. 2013). In the gold mines of South Africa, widespread use of IPT reduced TB incidence at the individual level while on therapy, but had no impact on TB rates at the population level, perhaps because of the exceedingly high rates of TB transmission and the corresponding risk of reinfection (Churchyard et al. 2012). While IPT has clear individual-level benefit for people living with HIV, its population-level impact as a public health measure depends on the logistic feasibility of delivery and the ongoing risk of TB reinfection after completing IPT. In areas where IPT can be effectively delivered, and the risk of TB reinfection is low, IPT is likely to have an important population-level impact on TB incidence. However, in areas where the annual risk of TB infection is high, IPT likely must be delivered consistently and continuously to achieve meaningful reductions in incidence. Future strategies for IPT delivery among people living with HIV in hyperendemic settings will need to balance the clear individual benefit against the less dramatic public health impact and relative logistical difficulty of implementation.

In summary, tremendous strides have been made in the public health approach to HIV-associated TB. Nevertheless, tremendous challenges remain as we begin to understand the limits of integrated care, ART, and IPT in controlling epidemics of HIV-associated TB. As ART extends life expectancy and the number of people living with HIV continues to grow, innovative public health approaches—such as those built on the models of early ART and continuous IPT—will need to be developed if we are to stem the tide of TB in areas of high HIV prevalence.

TB infection control

One area of need, and potential, for improvement in the public health response to TB is infection control especially in congregate settings such as prisons and healthcare facilities. These settings, particularly those with a high prevalence of HIV, pose tremendous risk for TB transmission and outbreak, as they introduce

individuals with infectious TB into crowded settings with other immunocompromised patients. Assuming that smear-positive TB is five times more infectious than smear-negative TB and that the effective contact rate in a hospital is 40 times higher than in the community, a hospitalized smear-positive patient could generate as many TB infections in 1 week—and to patients at much greater risk of TB progression and death—as a smear-negative counterpart in the community could generate in four years. Infection control measures for TB include measures that are administrative (e.g. rapid diagnosis, isolation, and treatment of individuals with infectious TB), environmental (e.g. ventilation and reduction of crowding), and respiratory/personal protective (e.g. masks and personal respirators) (Jensen et al. 2005). When all three of these tiers are instituted, infection control measures are very effective. For example, after implementation of aggressive infection control measures following an MDR-TB outbreak at a hospital in Florida, the number of nosocomial cases of MDR-TB fell from an average of 3 per month to no new cases (other than reactivation from infections acquired prior to the intervention) over a 2-year period (Wenger et al. 1995). Similar success was seen in reducing nosocomial transmission after improving infection control measures following an outbreak of extensively drug-resistant TB in KwaZulu-Natal, South Africa (Gandhi et al. 2013). The ability of simple measures, such as improved ventilation by opening windows, to reduce household transmission of TB is of increasing interest as well, and our ability to evaluate the effectiveness of such interventions is improving with the availability of mobile household environmental monitors.

Nevertheless, despite the demonstrated efficacy of infection control measures and the need to protect healthcare workers from TB (Joshi et al. 2006), infection control remains relatively poorly implemented. As of 2008, no country had reported data on implementation of infection control measures to the WHO (WHO 2009). Solutions to difficult challenges in TB infection control (e.g. improving ventilation when outside temperatures are cold) are rarely discussed in the literature. Similarly, due to a lack of research intensity, our understanding of even basic epidemiology related to infection control remains limited. Ultimately, infection control remains a globally neglected component of the public health response to TB, requiring greater attention if we are to avert the tremendous morbidity and mortality associated with outbreaks and transmission in congregate settings.

Health systems and gender issues in TB control

National tuberculosis programmes (NTPs) are key elements to control tuberculosis, but weak and overburdened health systems have impeded progress. In addition, rapidly introduced health system reforms and poorly designed systems have adversely affected national efforts to control TB. Innovative, geographically specific health systems strengthening should complement other strategies to control TB (Atun et al. 2010; Lienhardt et al. 2012). NTPs operate within the general health system, and both impact on each other. In many high TB-burden countries, NTPs operate within weak, overburdened health systems. As a result, TB programmes are likely to benefit from the strengthening of health systems, particularly in the areas of financing, policy development, human resource management, procurement of supplies and drugs, and maintenance of health infrastructure (El-Sadr et al. 2009). Many low- and middle-income countries experience human resource

constraints, which include inadequate human resource planning, insufficient numbers of skilled and motivated staff, high turnover, and inequitable distribution of staff (e.g. urban/rural, public/private, and HIV versus TB programmes). Inadequate human resources in many high-burden countries have been identified as an important constraint in achieving TB control targets. Because healthcare worker shortages may compromise TB programmes, TB-HIV integration and task shifting has been adopted as a strategy in which less skilled community workers take on tasks such as adherence counselling, defaulter tracing and family support (Samb et al. 2007; Maher 2010).

Conversely, strengthening national TB programmes may contribute to improvements in the general health system, including areas such as human resources, laboratory infrastructure, drug forecasting, data monitoring, supervision, and quality assurance (Stop TB Partnership 2008). Examples of how the NTP may strengthen the general health system include: applying microscopes purchased for sputum smear examination to malaria smears and urinalysis; using vehicles for district supervisory support also for supervision of health posts and clinics; and adapting the TB drug procurement and distribution system to drugs for chronic diseases. The Stop TB Partnership's Global Plan to Stop TB, 2006–2015, and a Stop TB Policy Paper create a framework for using TB control activities to strengthen general health systems (Stop TB Partnership 2008, 2011a). However, implementing this policy framework in a way that achieves the desired synergy between TB programmes and general health systems remains an ongoing challenge.

Epidemiologically, women in most resource-limited settings have a risk of TB half that of men. However, among younger age strata and in settings of high HIV prevalence, women often have higher TB incidence than men. Similarly, the prevalence of undiagnosed TB (and HIV) among pregnant women is unacceptably high (Gounder et al. 2011). Women often face specific challenges in accessing TB care (e.g. travel with children for directly-observed therapy) and are more likely than men to experience TB associated stigma. On the other hand, maternal and child services are often stronger than other aspects of healthcare systems, and men may, in many cases, have poorer access to general health services (including TB care) than women. As a result, TB may go undiagnosed for longer periods of time in men than in women, a finding that is suggested by TB prevalence surveys (Corbett et al. 2009). An effective TB response should therefore not neglect the unique considerations faced by members of either gender.

Financial constraints

Tuberculosis control is threatened by four key financial factors: (1) inadequate funding, (2) poor capacity to acquire financing, (3) management of funding from numerous sources, and (4) financial constraints to patient access. It was estimated that US\$56 billion would be required to achieve the MDG 6 objective for TB control and the Stop TB Partnership's goal of a 50 per cent reduction in the prevalence and mortality of TB by 2015. To address some of these challenges, global and philanthropic organizations have increased financial support for high-burden countries, new financing systems have been introduced to direct substantial funds to countries, and patient access has improved by centralizing and incorporating TB services into primary healthcare (Atun et al. 2010). Despite these interventions, escalating

financial needs, drug-resistant TB and migrant populations pose further risk to the control of TB in some areas.

Social determinants

Ninety five per cent of TB cases and 98 per cent of TB deaths occur in developing countries. Since TB affects the economically active age group (15–49 years), it has a direct impact on the economy of poor countries. High TB treatment interruption rates can be attributed to competing priorities of the need to earn money versus access to care (Benatar and Upshur 2010). The impact of poverty, overcrowding, and poor living conditions on TB control efforts should not be underestimated (Lienhardt et al. 2012). Urbanization, migration, and political instability create a fertile environment for TB to flourish. This is further complicated by increasing prevalence of smoking and substance abuse. TB control is inextricably linked with multifaceted efforts to alleviate poverty and promote economic development. Overcoming these challenges requires social support which is often lacking in the communities most affected by TB (Benatar and Upshur 2010).

Engagement with civil society organizations

Civil society organizations include non-governmental, community-based, and faith-based organizations. Their main role is to champion the rights of the vulnerable. Effective partnership and meaningful engagement of civil society organizations have a pivotal role in the response to the TB epidemic (Getahun and Raviglione 2011). Such organizations can influence not only community structure but also government institutions. They are able to function in remote areas and offer a unique opportunity for scaling up of community based care for TB-HIV (Ghebreyesus et al. 2010).

New tools for tuberculosis control

New diagnostic tests

Novel diagnostics are a key emerging weapon in the global fight against TB. It has been estimated that an effective rapid diagnostic test could reduce TB incidence by 20 per cent or more (Dowdy et al. 2006; Keeler et al. 2006), and be highly cost-effective (Dowdy et al. 2008). Novel tests for active TB include liquid culture systems, molecular diagnostic platforms (e.g. Xpert MTB/RIF[®] assay, and urine antigen assays for lipoarabinomannan (LAM)). The microscopic observation drug susceptibility (MODS) assay was introduced as a culture technique that is similar in accuracy and speed to automated liquid-media culture (e.g. Mycobacteria Growth Indicator Tube, MGIT[®]), but less resource-intensive (Moore et al. 2006). The MODS assay works on the principle of identifying ‘microcolonies’ of TB, which are visually distinct from those of other bacteria and mycobacteria. The sensitivity and specificity of MODS for pulmonary TB has been reported at 96 per cent, with a mean time to positivity of 9 days and material/supply costs of less than US\$2 per test. MODS also allows for first-line drug susceptibility testing. The primary challenges associated with microcolony culture are the requirement for a quality-assured, biosafety containment laboratory, delay in diagnosis of over a week, and difficulty in bringing non-automated, relatively labour-intensive techniques to scale. Automated liquid culture is more easily scaled up, but also substantially more expensive.

By contrast, the Xpert MTB/RIF[®] system is a fully-automated molecular (polymerase chain reaction (PCR)) test for active TB that provides results in 90 minutes with minimal human-resource input and similar biosafety requirements as sputum smear microscopy (Boehme et al. 2010). Recommended by the WHO for use in settings of high HIV prevalence or drug resistance, the sensitivity of Xpert MTB/RIF[®] for smear-positive TB is greater than 99 per cent. The specificity of Xpert MTB/RIF[®] is similarly high, but its sensitivity for smear-negative pulmonary TB is approximately 75 per cent in symptomatic patients (Boehme et al. 2011), and lower in prevalence surveys. Xpert MTB/RIF[®] can rapidly detect resistance to rifampin with sensitivity and specificity of 98 per cent or higher, thus facilitating immediate initiation of MDR-TB treatment in areas of high MDR prevalence. The primary limitations of Xpert MTB/RIF[®] are its requirement for climate control, stable electrical supply, and ongoing machine maintenance, and it is costlier (though more sensitive) than sputum smear. Nevertheless, a comprehensive analysis found Xpert MTB/RIF[®] to be cost-effective in most settings (Vassall et al. 2011).

Detection of LAM, a mycobacterial cell wall component, in urine is a novel diagnostic strategy with greatest utility in individuals with severe immune compromise. An assay is now available in a true point-of-care (lateral flow) format at a cost of US\$3 per test, providing results within 30 minutes. The sensitivity of this assay has been reported as 67 per cent in patients with CD4 T-cell counts of less than 50 cells/mm³, with specificity of greater than 98 per cent (Lawn et al. 2012). Sensitivity is unacceptably low in immunocompetent individuals, but this assay nonetheless improves markedly on the sensitivity of sputum smear microscopy in its target population, who are also the people for whom immediate diagnosis is potentially most important.

Interferon-gamma release assays (IGRAs) are blood tests that detect specific immune responses to *M. tuberculosis* (and not BCG), and have similar sensitivity to the TST but improved specificity (Pai et al. 2008). IGRAs have poor predictive value for incident active TB (Rangaka et al. 2012), and their use in serial testing (e.g. healthcare worker screening) is complicated by frequent conversions and reversions of uncertain significance. Because of their expense relative to TST, IGRAs are not recommended for use in resource-limited settings. Nevertheless, they are useful for detection of latent TB infection in some (mostly low-incidence) settings where the labour cost of placing and reading a TST is greater than the cost of the IGRA. Commercial serological antibody tests that are widely marketed for diagnosis of active TB demonstrate very poor accuracy, and the WHO issued a ‘negative’ recommendation against their use.

The line probe assay is a novel molecular test that uses PCR for TB drug susceptibility testing from clinical specimens and culture isolates. The most widely-used line probe assay, the Hain GenoType[®] MTBDRPlus assay, has a sensitivity of 98 per cent for rifampin resistance and 90 per cent for isoniazid resistance when used on smear-positive sputum specimens or culture isolates, and can provide results within a day (compared to 7–10 days for traditional phenotypic testing in culture) (Hillemann et al. 2007). This technology has recently been expanded to test for resistance to second-line drugs as well, with similar sensitivity (around 90 per cent) for amikacin/capreomycin and fluoroquinolones (Hillemann et al. 2009).

Although these novel tests add substantial value to the public health armamentarium against TB, each assay is limited in some important fashion. A true stand-alone, point-of-care test for active TB that is suitable for use in a broad population remains elusive. Ultimately, new diagnostic tests do not function in isolation, but rather serve as one component of a broader system that also consists of patient and provider preferences, treatment decisions, public health infrastructure, and linkage to care. In developing and using new diagnostics for TB control, it is important to evaluate not only their sensitivity and specificity, but also their ability to improve TB outcomes (morbidity and mortality) when functioning as part of that system.

New drugs

The current first-line treatment for TB is more than 30 years old and relies on drugs developed 40–60 years ago. It is apparent that new drugs and regimens that kill bacilli rapidly and sterilize populations of *M. tuberculosis* are urgently needed to confront the problems of TB control in the twenty-first century. The highest priority for new drugs is for agents to more effectively treat MDR and XDR-TB, as current therapies rely on toxic second-line drugs that must be taken for up to 2 years and only cure 50–70 per cent of patients (WHO 2010b). The development of more potent first-line regimens for the treatment of drug-susceptible TB will cure patients faster, reduce the duration of therapy improve adherence to therapy, improve cost-effectiveness (Owens et al. 2013), and free TB control staff to treat greater numbers of patients. More potent agents may improve the treatment of latent TB, permitting patients to take shorter courses of more potent drug/s than the 6–9 months currently required for isoniazid preventive therapy. For example, a 12-week, once-weekly course of rifapentine plus isoniazid was recently shown to be equally (if not more) effective as 9 months of isoniazid (Sterling et al. 2011).

Drugs for TB have traditionally been grouped into five categories based on their priority for use in drug-susceptible and drug-resistant TB rather than their mechanism of action (Table 8.14.1). Research into new classes of antimicrobial agents with novel mechanisms of action has led to the identification of new drugs with the potential to transform the treatment of both drug-susceptible and drug-resistant TB. Class 1 includes the current first-line drugs used for treating TB. Class 2 is the injectable agents which require intramuscular or intravenous administration, of which all except streptomycin are used in treatment of MDR TB. Class 3, the fluoroquinolones, are potent inhibitors of mycobacterial replication and may help shorten treatment of all forms of TB. Class 4 comprises older drugs that were previously used in first-line regimens but which were relegated to second-tier status because of low potency and higher toxicity. Class 5 is an assortment of unrelated drugs that are used in the treatment of some drug-resistant TB cases and have varying strengths of evidence.

We have added Class 6, a small but hopefully growing list of new agents developed to exploit novel targets in the mycobacterial life cycle, many of which are in advanced stages of clinical development. The newest approved drug for treating TB is bedaquiline, a drug that targets bacterial adenosine tri-phosphate synthase, which was shown in a phase 2 trial to double rates of culture conversion among patients with MDR-TB

(Diacon et al. 2012). Another new drug, delamanid, targets at least two steps in mycobacterial replication and metabolism and has been shown to be effective in patients with MDR-TB (Skripconoka et al. 2013). The other agents listed have all shown promising activity and are in varying stages of development for clinical use.

The promise of new TB vaccines

TB vaccines aim to reduce the risk of TB by preventing infection and reducing the risk of progression to TB disease. The current TB vaccine, BCG, the most widely used vaccine worldwide, protects children from disseminated disease but has had negligible impact on the global TB epidemic (Kaufmann 2011). The efficacy of BCG against pulmonary TB in adults is variable and ranges from –22 per cent (harmful) to +80 per cent (Rieder 2002). The efficacy of BCG varies according to vaccine strain used and geography. Environmental mycobacteria, helminths, and HIV infection (Hoft 2008) may modify vaccine-induced immune responses. The WHO recommends that BCG not be administered to HIV-infected infants as it may cause disseminated BCG disease (BCGosis) (Anonymous 2007). In order to accelerate progress towards eliminating TB as a global health threat, TB vaccines that are safe and effective in infants, adolescents, and adults are required. From a public health perspective, TB vaccines that will prevent infection as well as prevent reactivation of latent TB infection and progression to TB disease will have greatest population-level impact.

Major advances have been achieved in vaccine development making the availability of new vaccines foreseeable within the next decade. Many current vaccine strategies aim to induce TB specific T-cell immunity using disease-stage specific antigens (Lambert et al. 2009). Such ‘pre-exposure’ vaccines in development aim to replace BCG with a safer alternative, particularly for HIV-infected infants (McShane 2011). Strategies include recombinant BCG strains, attenuated *M. tuberculosis*, and whole-cell killed mycobacteria. All current pre-exposure vaccine candidates are designed to avert disease but will neither eradicate the pathogen nor prevent latent infection. Next-generation vaccines should attempt to both prevent TB infection and eradicate established latent TB infection (Kaufmann 2010). Another approach attempts to boost immunological memory induced by an initial priming vaccine (i.e. ‘prime-boost’ strategy) to improve and prolong protection. Such booster vaccines may be applied either in infancy soon after BCG vaccination, or later in adolescence when the risk of exposure to TB increases. ‘Post-exposure’ vaccines to prevent reactivation in latent infection target antigens and immunity pathways different from pre-exposure vaccines (Kaufmann 2011). Therapeutic vaccines administered adjunctively with treatment to shorten the duration of treatment and perhaps increase the efficacy of chemotherapy are also being clinically tested (Lambert et al. 2009; McShane 2011).

A major obstacle to vaccine development is our lack of knowledge of the immunopathogenesis of TB; better animal models that more accurately represent human disease and biomarkers indicating a protective immune response are urgently needed. Until biomarkers are available, more suitable clinical end points of TB disease and infection, particularly for paediatric and HIV-associated TB, would be invaluable assets in the effort to develop novel and effective vaccines.

The future of tuberculosis control: is elimination achievable?

TB elimination is defined as one case per million population. In order to achieve elimination, TB incidence globally will need to be reduced 1000-fold and in some high burden countries by 10,000-fold (Dye et al. 2005). Although much progress has been made under the current Stop TB plan (2006–2015), the rate of decline of TB disease globally is far from what is required to achieve TB elimination by 2050. An important milestone marking entry into the elimination phase, globally and nationally, is having fewer than ten TB deaths per million population. Encouragingly, using this definition, 35 countries and territories with populations in excess of 100,000 are already in the elimination phase, and many more could enter in the next one to two decades by simultaneously reducing TB case incidence and fatality (Dye et al. 2013). A comprehensive approach is required to achieve TB elimination by 2050 globally, particularly in high-burden countries. In New York City, TB case rates almost tripled between 1978 and 1992 and ‘turning the tide’ of TB was largely attributed to increased funding allowing better attention to the fundamentals of TB control (Frieden et al. 1995). These fundamentals—which can be addressed with existing technologies and should underpin all efforts to improve TB control—include health system strengthening, improved detection of persons self-presenting to health services, rapid and complete treatment initiation following diagnosis, improved cure rates, and universal access to care. These basic elements of TB control, while a necessary first step, will be inadequate to achieve elimination, however. Mathematical modelling suggests that augmenting these strategies with new TB drugs, diagnostics and vaccines may have an important impact on the global TB epidemic (Abu-Raddad 2009). The post 2015 Stop TB plan will focus on developing new tools and innovative strategies required to accelerate progress towards TB elimination by 2050. The priority areas of research to accelerate progress towards TB elimination are described in the Stop TB Research Roadmap (Stop TB Partnership 2011b). In order to maximize the population level impact, the new tools will need to be scaled up rapidly, with high coverage and combined with a range of other evidence-based interventions. The combination of intervention strategies that are likely to be effective in a given population will vary according to the relative proportion of underlying risk factors. The ‘Know Your Epidemic/Know Your Response’ approach requires knowledge of the TB epidemic in a country in order to select the most appropriate combination of interventions for that country.

Mathematical modelling can assist countries in assessing the relative effectiveness and cost effectiveness of different combinations of interventions. Modelling suggests that in high burden countries with high HIV prevalence, such as South Africa, preventing TB among HIV-infected persons must also be prioritized, and in high-burden countries with a low HIV prevalence, such as India and China, scaling up early case detection and treatment should be coupled simultaneously with treatment of latent TB infection in HIV-uninfected persons (Fig. 8.14.4) (Dye et al. 2013). In countries in the elimination phase, such as in Western Europe and the United States, modelling suggests that maintaining low rates of transmission while preventing

reactivation TB among native populations while simultaneously preventing TB among foreign-born populations that account for the majority of cases, is required to achieve elimination of TB (Fig. 8.14.4) (Dye et al. 2013).

Conclusions

Over the past decade, for the first time in history, the number of new incident TB cases has started to decline worldwide. This momentous accomplishment can be attributed to an unprecedented scale-up of basic TB control measures, including access to diagnosis through sputum smear microscopy, use of effective drug therapy, and measures to prevent TB transmission and disease. Nevertheless, we remain far from the target of eliminating TB as a public health problem by 2050. Particular challenges include control of TB in key populations such as people living with HIV, individuals infected with drug-resistant TB, and children. Other groups at particularly high risk of TB transmission and disease include individuals living in mines, prisons, and impoverished areas; control measures in these populations are often inadequate. As TB control advances into the next decade, aggressive scale-up is needed of measures that can effectively fight TB in these populations, including active case finding in high-risk populations, antiretroviral therapy, TB preventive therapy, and infection control to prevent healthcare-associated transmission. If we are to achieve the goal of global TB elimination, existing technologies alone are likely also to be inadequate; better diagnostic tests, first- and second-line drugs, and eventually vaccines will be required. Public health leaders are beginning to envision a world free of TB—but this ambitious goal is still far from our present grasp. Only with increased funding, research, and innovation, coupled with political commitment and global attention to the fundamentals of TB control (detection, treatment, and prevention), can this vision be realized.

This chapter has outlined the epidemiology, public health approach, and future prospects for control of TB worldwide, demonstrating how existing tools have been used to turn the tide of TB incidence and bring discussion of TB elimination to the table. For the first time in more than 20 years, we also have the simultaneous promises of new first-line diagnostic tests for TB, new drugs and treatment regimens for TB, and a healthy pipeline of potential TB vaccines. Enhanced public health strategies for TB control—including active TB case finding and isoniazid preventive therapy—are finding wider use globally than ever before. Millions of people continue to die of TB every year, and we as a public health community must fulfil our obligation to continually strengthen the response to this ancient scourge until the number of TB deaths is brought to zero. To achieve this goal, however, a coordinated and comprehensive public health response will be required.

Malaria

Frank Sorvillo, Shira Shafir, and Benjamin Bristow

Introduction to malaria

Malaria remains one of the most important and intractable global public health problems. It is not hyperbole to suggest that this parasitic disease may be the most prolific killer of humans in history and its continuing impact is difficult to overstate. Currently an estimated 99 countries are affected by malaria with approximately 40 per cent of the world's population exposed to this preventable disease (World Health Organization (WHO) 2012).

Deadly periodic fevers, probably malaria, have been known since antiquity, yet it wasn't until the late nineteenth century that the cause and mechanism of transmission were elucidated (Harrison 1978). Alphonse Laveran, a French Army physician serving in North Africa, first identified the intraerythrocytic protozoan parasite, *Plasmodium*, in 1880 from the blood of a soldier with acute malaria. Seventeen years later Ronald Ross, a British physician serving in India, with painstaking effort, identified the 'dapple-winged' *Anopheles* mosquito as the vector. Both Laveran and Ross were awarded a Nobel Prize in Physiology or Medicine for their work.

Malaria is a complex and daunting problem with an intricate life cycle and nuanced interplay of agent, host, vector, and environment that is further complicated by challenging political, economic, and social factors (Bremner 2004). This chapter provides an overview of the relevant aspects of malaria focusing principally on the key public health-related issues including estimates of the current burden, description of the agent, life cycle, modes of transmission and vector aspects, discussion of epidemiological factors, basic information on clinical manifestations, diagnostic testing, treatment and chemoprophylaxis approaches, and delineation of control measures. Current challenges, controversies, and future directions are also presented.

Malaria agent

Malaria is caused by protozoal organisms of the genus *Plasmodium* (Beaver et al. 1994; Centers for Disease Control and Prevention (CDC) 2010a). While there are more than 100 species of *Plasmodium*, which can infect many animals such as reptiles, birds, and various mammals, historically, only four species of *Plasmodium* were recognized to infect humans in nature. A fifth species of malaria, the primate parasite *P. knowlesi*, though first known to cause infection in humans in 1967, has recently emerged as an important cause of zoonotic malaria in South East Asia (Antinori 2013). These five species of malaria differ in geographic distribution, clinical manifestations, and details of their life cycle. The most important species in terms of virulence and global

burden is *P. falciparum*, which accounts for the vast majority of deaths. However, the impact of *P. vivax* has been increasingly recognized as considerable. *P. ovale* and *P. malariae* have more limited distribution and significance.

Life cycle

The life cycle of malaria is complex, slightly different for each species, and necessarily involves both humans and *Anopheles* mosquitoes (Aly et al. 2009; CDC 2010a). When a human host is bitten by a malaria-infected mosquito, sporozoites are inoculated (Fig. 8.15.1). The sporozoites will travel via the blood and infect liver cells where they will mature into schizonts containing large numbers of merozoites. In the case of *P. vivax* and *P. ovale*, hypnozoites, a dormant stage, can persist in the liver and, if not appropriately treated, can cause relapse by releasing merozoites into the bloodstream weeks, months, and rarely years later. The entire process of initial replication in the liver is referred to as exoerythrocytic schizogony. After this process is complete, schizonts will eventually rupture and release merozoites that will enter red blood cells (RBCs). In a process known as erythrocytic schizogony, merozoites initially form small ring stages, then larger trophozoites, and subsequently form erythrocytic schizonts via asexual replication. These schizonts rupture, releasing merozoites, which invade other erythrocytes. The cycle of rupturing merozoites will eventually synchronize, flooding the bloodstream with parasitic material, resulting in many of the clinical manifestations of infection. For *P. falciparum*, *vivax*, and *ovale*, this happens in a 2-day cycle (CDC 2010b). In the case of *P. malariae*, the cycle follows a 3-day course, while *P. knowlesi* has a 24-hour cycle. Some of the merozoites will differentiate into gametocytes (macrogametocytes and microgametocytes), the sexual erythrocytic stage, which can infect mosquitoes.

If an infected human is bitten by a susceptible *Anopheles* mosquito, the microgametocytes and macrogametocytes will be ingested and the sporogonic cycle will begin (CDC 2010a, 2010b). In the stomach of the mosquito, the microgametes will fertilize the macrogametes and a zygote will be formed. The motile, elongated zygote, known as an ookinete, will invade the midgut wall of the mosquito and develop into an oocyst. The oocyst will enlarge and eventually rupture releasing sporozoites which will migrate to the salivary glands of the mosquito and be available to infect another host. The complete cycle in the mosquito takes approximately 10–18 days, a period termed the extrinsic incubation cycle or extrinsic cycle. When the infected mosquito feeds, sporozoites will be inoculated into the human host, and the cycle will begin anew.

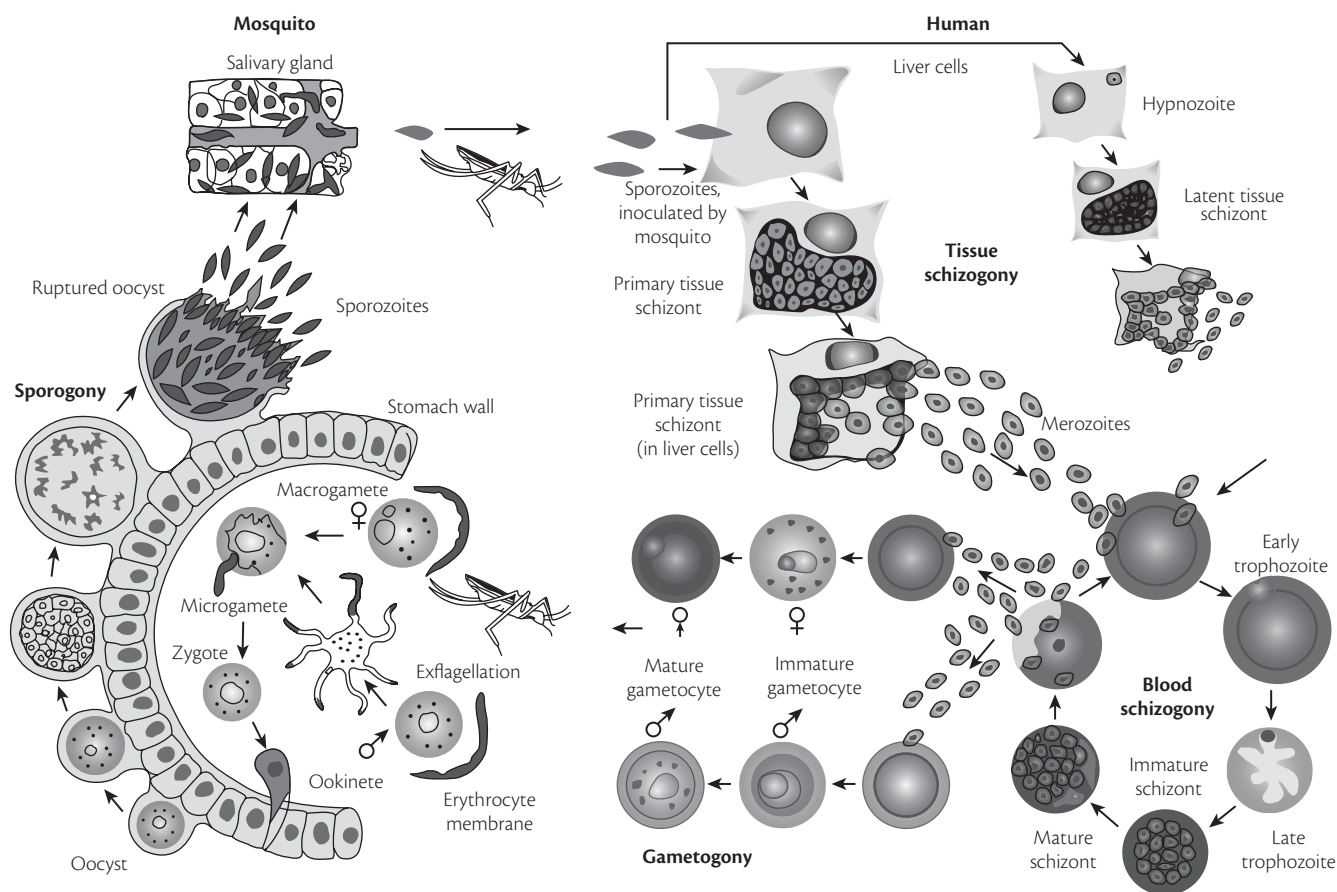

Fig. 8.15.1 Life cycle of malaria parasite.

Transmission

Transmission of the malaria parasite occurs through the bite of an infected female *Anopheles* mosquito (CDC 2012). Only female adult mosquitoes of the *Anopheles* genus play a role in malaria transmission as they are the only ones who take a blood meal, since they require the protein and iron from the blood for egg development. Male mosquitoes feed on nectar and other sources of sugar and therefore do not transmit malaria. Most *Anopheles* species are either nocturnal or crepuscular and consequently the highest risk of malaria transmission is from dusk until dawn. Malaria transmission can occur anywhere there are infected humans, mosquitoes that are capable of being infected, and contact between the two.

As with all mosquito species, anophelines have four stages in their life cycle which include egg, larva, pupa, which are aquatic stages, and the adult (Beaver 1984; CDC 2012). The adult female lays approximately 50–200 eggs that are deposited singly in water sources where they hatch in 2–3 days into larvae which will subsequently moult into pupae. Both larvae and pupae breathe through spiracles and must come to the surface frequently. After a few days the adult mosquito emerges. The time from egg to adult varies by species and ambient temperature but typically takes 5–14 days in tropical conditions. Anophelines can utilize diverse water sources for breeding.

The species of *Anopheles* present in an area at a given time will influence the intensity of malaria transmission (Sinka et al. 2012). Different *Anopheles* species have different capacity to serve as a malaria vector. Out of over 400 *Anopheles* species, only 30–40 are easily infected and will produce large numbers of infectious sporozoites that they can subsequently transmit when they feed on susceptible humans. Table 8.15.1 presents selected major malaria vectors by geographic regions.

Additionally, the feeding preferences and resting behaviour of the mosquito can have a significant impact on the ability to effectively transmit malaria (Beaver 1984; CDC 2012). Anthropophilic mosquitoes, species that preferentially feed on humans such as *Anopheles gambiae*, tend to be the most effective vectors. Zoophilic mosquitoes, species that preferentially feed on non-human animals, tend to be less effective. Mosquitoes that prefer to feed inside (termed endophagic) also tend to be more effective vectors than those that are exophagic, preferring to eat outside, simply because they are likely to have greater contact with humans. Resting behaviour of the mosquito is also important because of the impact that it can have on control strategies. Mosquitoes that prefer to rest inside (termed endophilic) after they have taken a blood meal will be more likely to be effectively controlled by indoor residual spraying than those that prefer to rest outside (exophilic) after their blood meal (Shiff 2002).

Table 8.15.1 Selected major malaria vectors by geographic region

Region	Vector species
Africa	<i>Anopheles gambiae</i> <i>An. arabiensis</i> <i>An. funestus</i>
South America	<i>An. darlingi</i>
Central America	<i>An. albimanus</i> <i>An. pseudopunctipennis</i>
India	<i>An. culicifacies</i> <i>An. stephensi</i> <i>An. fluviatilis</i>
South East Asia	<i>An. dirus</i> <i>An. minimus</i>
Indonesia	<i>An. sinensis</i> <i>An. barbirostris</i> <i>An. leucosphyrus</i> <i>An. minimus</i>
New Guinea	<i>An. farauti</i> <i>An. koliensis</i> <i>An. punctulatus</i>

Occasionally mosquito-borne transmission of malaria in non-endemic areas has occurred, typically in small foci when parasitaemic individuals from endemic areas are bitten by competent local vectors and subsequently transmit infection (CDC et al. 2006). In addition, exposure to infected vectors that are transported to non-endemic countries may also occur typically as 'airport malaria' (Thang et al. 2002).

In certain rare cases, malaria can be transmitted in the absence of the *Anopheles* mosquito. It can be passed congenitally from infected mother to child (vertical transmission) as well as through transfusion, organ transplantation, and needle sharing (CDC 2010c). To prevent transmission of malaria via transfusion, in most developed countries individuals are deferred from blood donation for a period of 1 year following travel to a malarious region.

Epidemiology

Many factors involving host, environment, and vector can impact the epidemiology of malaria.

Host

Susceptibility to malaria is an important host-related factor that influences malaria transmission dynamics. In areas of high malaria transmission intensity with repeated exposure to the parasite, a level of partial immunity will develop and severe infections are seen predominantly in children, whereas most adults will be asymptomatic. In areas of lower transmission intensity all ages can be affected (Doolan et al. 2009; CDC 2010d). Individuals who are semi-immune may not develop severe disease, or any symptoms at all; however, they can still be infected and therefore serve as a source of infection for others. Without repeated exposure to the parasite, partial immunity will wane. Individuals who were

born in a malarious region and then move away may be vulnerable if they return and therefore should be strongly encouraged to take malaria prophylaxis. Additionally, this partial immunity passes from mother to child *in utero*; however, passive immunity wanes and this leaves children aged 6 months to 5 years the most vulnerable to infection with malaria since they are no longer protected by maternal antibodies and they have not yet survived repeated infections to develop partial immunity of their own.

As a result of selection pressure several human genes share a distribution that is very similar to that of malaria. Many of these genetic traits provide substantial protection against malaria via a number of different mechanisms (Taylor et al. 2012). Individuals who are heterozygous for the abnormal haemoglobin gene HbS, those who possess the sickle cell trait but not sickle cell disease, are relatively protected against *P. falciparum* malaria because the parasite has difficulty entering into the abnormally shaped RBCs. This has led to the persistence of the sickle cell trait in sub-Saharan Africa. Several other haemoglobin-related disorders and other blood cell dyscrasias, such as haemoglobin C, alpha and beta thalassaemias, and glucose-6-phosphate dehydrogenase (G6PD) deficiency, have increased prevalence in malaria endemic areas and are thought to provide some degree of protection from the parasite. Other haemoglobinopathies that have been shown to be protective against malaria include haemoglobin E and haemoglobin F.

Inherited abnormalities of red cell surface antigens and cytoskeletal proteins may also protect against malarial infection (Taylor et al. 2012). For example, individuals who are negative for the blood group antigen Duffy, are resistant to infection with *P. vivax* as the antigen is used by the parasite for intracellular invasion of the RBC. In the specific case of *P. vivax*, individuals who lack the Duffy blood group are resistant to infection. *P. vivax* is extremely rare in sub-Saharan Africa, particularly West Africa, since most Africans are Duffy negative. Other genetic factors related to RBCs may also influence either the risk of acquiring malaria or the risk of developing severe disease once infected, but these factors are not as important.

Pregnant women and the unborn fetus experience a number of risks and complications associated with malarial infection (Steketee et al. 2001; Guyatt and Snow 2004; ter Kuile et al. 2004; Nahlen et al. 2005; Desai et al. 2007; Dellicour et al. 2010). Since pregnancy reduces immunity, women who have developed partial immunity against *P. falciparum* tend to lose protection that they previously developed. This phenomenon is particularly noteworthy in the first and second pregnancies. Peripheral parasitaemia is higher in pregnant than in non-pregnant woman living in the same geographic areas. In endemic areas, the prevalence of malaria generally decreases with increasing gravidity, but remains higher in pregnant women of any gravity compared to non-pregnant woman. Compared to non-pregnant women, pregnant women experience more severe disease, more hypoglycaemia, and more respiratory complications. Anaemia is a common complication of malaria in pregnancy.

A unique feature of malaria in pregnancy is the ability of *P. falciparum* parasitized RBCs to sequester and multiply within the intervillous space of the placenta. Placental infection may be present even in the absence of peripheral parasitaemia. Placental malaria is associated with a number of poor outcomes including miscarriage, preterm birth, low birth weight, perinatal mortality, and congenital malaria from vertical transmission.

Increasing human population density provides additional hosts for vector mosquitoes and increases the probability of contact. Greater prevalences of malaria and higher parasitaemia, particularly gametocytes, increase the likelihood that a mosquito blood meal results in infection of the vector and subsequent transmission. Behavioural factors such as night-time work that occurs outdoors, and travel to a malarious area, through either tourism or voluntary or forced migration, which would expose non-immune individuals, can also increase risk for malaria infection.

A number of key ancillary factors including economics, which impact housing, availability of local healthcare, and existing control measures, as well as movement of populations and conflicts may affect malaria transmission.

Environment

Climatic conditions, including temperature and rainfall, can have substantial effects on malaria (Paaijamns et al. 2009). Increasing temperatures shortens the duration of the extrinsic cycle in the vector making the mosquito infectious more quickly and increasing the probability of transmission (Beaver et al. 1984; CDC 2012). Excessive heat may make the use of bednets uncomfortable and thereby reduce usage. Rain can create additional breeding sites for *Anopheles* mosquitoes and increase the density of vectors. However, in some circumstances, excessive rain may actually wash away breeding areas. The presence of water for irrigation around villages and houses, plays a major role in determining the risk of malaria (CDC 2010e). In some areas malaria transmission is driven by seasonal changes of the climate with the transmission and incidence being the highest in the rainy season. Increasing altitude decreases the risk of malaria transmission and, at high enough elevation, vector populations cannot be maintained and the disease will therefore be absent (Bødker et al. 2003).

Vector

A number of key vector-related factors impact the epidemiology of malaria (Shiff 2002; CDC 2012). Vector competence, or the innate genetic factors that influence mosquito susceptibility to *Plasmodium* infection and subsequent ability of a vector to transmit a pathogen, is important and varies among species with some being totally refractory to infection. A related, but broader concept that has been used to conceptualize malaria transmission is vectorial capacity which integrates several important factors including vector density, host preference, and female mosquito longevity, as well as vector competence. Vectorial capacity, which is difficult to measure, can be assessed quantitatively as a function of the density of female anopheline mosquitoes relative to humans, the probability that a mosquito will feed on a human, the number of times a person is bitten, the proportion of the vector population that survives the extrinsic cycle in the mosquito, and the number of days this proportion is expected to survive (Shiff 2002). *An. gambiae*, an efficient malaria vector with high competence and vectorial capacity, is highly susceptible to infection, has relatively long survival, prefers to feed on humans (anthropophilic), feeds (endophagic) and rests (endophilic) indoors, and is active at night (nocturnal) (Cohuet et al. 2010). Given that the extrinsic cycle in the vector may be as long as 18 days, mosquito longevity is of particular importance.

The actual rate of transmission can be measured by the entomologic inoculation rate (EIR) which is the proportion of infected

mosquitoes, also known as the sporozoite rate, coupled with the mosquito biting rate, which can be estimated from mosquito density and human blood index surveys (Smith et al. 2006). This is a useful, and more readily obtained, measure of the intensity of malaria transmission.

Epidemics

Malaria epidemics frequently affect highlands and semi-arid areas where populations lack immunity (Abeku 2007). Most malaria epidemics follow abnormal weather conditions, often in combination with other causes, including increased resistance of the parasite to antimalarial drugs, population movement due to seasonal labour and civil unrest, and reduced malaria control operations, in particular, the cessation of regular vector control.

Clinical manifestations of malaria

The clinical manifestations of malaria vary with age, immunity, epidemiology, and geography. In highly endemic areas, the highest risk groups include children (age 6–36 months), who can develop severe illness, and pregnant women, who can deliver low birth weight newborns. In geographic regions where malaria is transmitted year round, older children and adults develop partial immunity after repeated infections and are at lower risk for severe disease.

Following the bite of an infected female *Anopheles* mosquito, patients are asymptomatic for approximately the first 12–35 days (depending on the *Plasmodium* species) until the parasite reaches the erythrocytic stage of its life cycle. The relapsing species of malaria (*P. vivax* and *P. ovale*) can present as a new infection months (and rarely years) after the initial exposure due to activation of hypnozoites in the liver (Imwong et al. 2007). The incubation period for *P. falciparum*, the species responsible for the vast majority of malarial deaths, is approximately 12 days, but may be longer in semi-immune individuals (Table 8.15.2).

Malarial fever

Early in the course of clinical malaria, febrile episodes occur at irregular intervals daily. The temperature of non-immune individuals and children may rise above 40°C (104°F) and can be associated with tachycardia, delirium, and febrile convulsions (in children). Later in the course of the infection (if untreated), the rupture of infected RBCs may become synchronized giving rise to febrile paroxysms every other day for *P. vivax*, *P. ovale*, and *P. falciparum*, and every third day for *P. malariae*.

Uncomplicated malaria

Uncomplicated malaria can occur with any *Plasmodium* species. The initial symptoms of malaria are non-specific and may include fever, tachycardia, tachypnoea, chills, malaise, fatigue, diaphoresis, headache, cough, anorexia, nausea, vomiting, abdominal pain, diarrhoea, arthralgias, and myalgias (Bremner et al. 2006). In general, patients without an altered mental status who can take oral medication have uncomplicated disease. Patients with uncomplicated disease may have a mild anaemia and a palpable spleen. Anaemia is common among children with malaria, but is often due to multiple causes in addition to malaria. Laboratory evaluation of uncomplicated malaria may demonstrate parasitaemia (usually < 0.1 per cent parasitized RBCs), anaemia, thrombocytopenia,

Table 8.15.2 Malaria species of humans

Species	Distribution	Incubation period	Persistent liver stage
<i>Plasmodium falciparum</i>	Africa, India, South East Asia, Indonesia, Oceania, South America, Central America, Middle East	7–27 days (average 12)	No
<i>P. vivax</i>	India, South America, Central America, Africa, Middle East	8–31 days (average 14)	Yes
<i>P. malariae</i>	Africa, South America, Central America, South East Asia	28–37 days (average 30)	No
<i>P. ovale</i>	Africa	11–16 days	Yes
<i>P. knowlesi</i>	South East Asia	9–12 days	No

elevated transaminases, mild coagulopathy, and elevated blood urea nitrogen (BUN) and creatinine.

Complicated/severe malaria

Most cases of complicated/severe malaria are due to *P. falciparum*; however, patients with complicated infection due to *P. vivax* have been described. Complicated malaria is generally defined as acute malaria with hyperparasitaemia (> 5–10 per cent of parasitized RBCs) and/or major signs of organ dysfunction (Devarbhavi et al. 2005). Many of the clinical findings are the result of the parasitized (and non-parasitized) RBCs adhering to small blood vessels in a process known as cytoadherence (Newbold et al. 1999). Cytoadherence causes small infarcts, capillary leakage, and organ dysfunction. The clinical findings may include altered consciousness (with or without seizures), acute respiratory distress syndrome, circulatory collapse, metabolic acidosis, renal failure, haemoglobinuria (blackwater fever), hepatic failure, coagulopathy (with or without disseminated intravascular coagulation), severe anaemia, massive intravascular haemolysis, and hypoglycaemia (Das 2008; Taylor et al. 2012). Patients with complicated malaria may have pallor, petechiae, jaundice, hepatomegaly, and splenomegaly (or rarely splenic rupture). Laboratory evaluation may demonstrate parasitaemia greater than 5–10 per cent, anaemia, thrombocytopenia, elevated BUN and creatinine, acidosis and hypoglycaemia.

Cerebral malaria

Cerebral malaria is an encephalopathy that presents with impaired consciousness, delirium, and/or seizures (Ponsford et al. 2012). Risk factors for cerebral malaria include no malarial immunity, age (young and elderly), pregnancy, poor nutritional status, HIV infection, and history of splenectomy. Cerebral malaria can rapidly progress to coma and death. If untreated, cerebral malaria is almost always fatal; with appropriate treatment mortality is 15–20 per cent. Laboratory evaluation of cerebral spinal fluid (CSF) may be normal or may have a slightly elevated total protein and cell count. Retinal haemorrhages and other ophthalmologic abnormalities may be observed. Survivors of cerebral malaria may have long-term neurological sequelae. This is more common in children than adults and may include hemiplegia, cerebral palsy, cortical blindness, deafness, epilepsy, language deficits, and impaired cognition.

A number of other important clinical manifestations can impact survival. Hypoglycaemia is common in complicated malaria and is associated with a poorer prognosis, especially in children and pregnant women. Acidosis is an important cause of death in severe

malaria. Its causes are multifactorial and severe acidosis carries a poor prognosis. Renal impairment is common amongst adults with severe malaria. Its causes are multifactorial. The urine may be dark coloured in cases with large amounts of haemoglobin and malarial pigments in the urine secondary to intravascular haemolysis. This uncommon condition is known as blackwater fever and carries a high risk of mortality (Das 2008). Children in endemic regions with multiple episodes of malaria may develop severe chronic anaemia. Non-immune individuals with acute malaria may also develop anaemia. The anaemia is due to haemolysis of parasitized RBCs, increased splenic clearance of RBCs, cytokine suppression of haematopoiesis, and shortened RBC survival. Mild jaundice due to haemolysis is common in malaria. Severe jaundice, with hepatocyte injury and cholestasis, may occur in severe infection. Liver dysfunction with renal impairment or other organ dysfunction is associated with a poorer prognosis. Septicaemia may complicate severe malaria, particularly in children.

Recrudescence or relapse

Recrudescence and relapsing infections manifest as return of disease after apparent cessation. In recrudescence, which occurs most often in days to weeks, parasites remain in the bloodstream undetected due to ineffective treatment or host immunological response. In relapse, which occurs most often in weeks to months, merozoites are released from ‘dormant’ hypnozoites of *P. vivax* or *P. ovale* and initiate the erythrocytic cycle.

Diagnosis of malaria

Prompt and accurate diagnosis of malaria, with species identification, is needed for the rapid implementation of appropriate treatment to reduce the risk of morbidities and mortality (Newman et al. 2004). Given the emergence of chloroquine- and, in some cases, mefloquine-resistant *P. falciparum*, accurate diagnosis is critical for the selection of appropriate treatment.

Clinical diagnosis of malaria is challenging, as there are no pathognomonic signs or symptoms of malaria. There are a growing number of studies demonstrating that clinical diagnosis of malaria is often incorrect. This can lead to the overuse of anti-malarial medications and can delay accurate diagnosis and treatment of other potentially life-threatening illnesses.

Light microscopy

Detection of parasites on Giemsa-stained blood smears by light microscopy is the gold standard for the diagnosis of malaria (Ash and Orihel 2007). The sensitivity of microscopy can be excellent,

even with very low percentage parasitaemias, when conducted by a skilled microscopist with adequate time to review each slide (minimum 20 minutes). Light microscopy allows for the determination of the infecting *Plasmodium* species as well as quantifications of parasitaemia, which can be used to monitor response to therapy. Given the cyclic nature of malaria parasitaemia, blood smears should be reviewed every 6–12 hours for 48 hours before the diagnosis of malaria is reliably ruled out. Light microscopy is labour intensive, time-consuming, and requires substantial training and expertise that may be unavailable in many low-resource settings.

There are two types of blood smear preparations: thin smears and thick smears. Thin smears allow identification of the species as well as measurement of parasite density. Thick smears are also useful for measuring parasite density, especially at low levels of parasitaemia, as the thick smear preparation results in the destruction of RBCs leaving the parasites concentrated so the microscopist can screen large quantities of blood for the presence of parasite. Detailed guidance on the differing morphological characteristics of the malaria species can be found elsewhere (Ash and Orihel 2007). In addition, an excellent set of bench aids for the diagnosis of malaria is available (WHO 2000).

Rapid diagnostic tests

Rapid diagnostic tests (RDTs) were introduced in the early 1990s and detect antigen by immunochromatographic lateral flow (Murray et al. 2008). A blood sample migrates across the surface of a nitrocellulose membrane by capillary action. The membrane contains stripes of antibodies specific for different epitopes of a target antigen (which is conjugated to an indicator), along with a control antibody (and conjugated indicator). Monoclonal antibodies tend to be more specific and polyclonal antibodies tend to be more sensitive. There are numerous RDTs available worldwide, some solely detect *P. falciparum*, and others can identify other *Plasmodium* species. Concern over poor sensitivity for detecting low parasitaemias and inadequate specificity, which can lead to false positives and poor positive predictive values in low prevalence areas, have plagued such tests.

However, the WHO has engaged in several rounds of testing commercially available RDTs against samples of low (200 parasites/microlitre) and high (2000 or 5000 parasites/microlitre) concentration (WHO 2012b). Across four rounds of assessment, several RDTs demonstrated high sensitivity with consistent detection of malaria at low parasitaemia levels and had low false-positive rates. Moreover, they are stable at tropical temperatures, are relatively easy to use, and can detect *P. falciparum*, *P. vivax*, or both.

Other techniques have been developed to improve the diagnosis of malaria; however, these methods are limited by a number of factors such as the need for specialized equipment and supplies, operator expertise, turnaround time, and cost.

Treatment and management of malaria

The treatment and management of malaria can be challenging and depends on the species of *Plasmodium*, the potential resistance, levels of parasitaemia, and clinical status. More detailed information is available from the WHO (2010).

Uncomplicated malaria

Uncomplicated malaria is typically treated with oral medications and does not require hospitalization. However, young children, non-immune adults, and immunosuppressed individuals can deteriorate rapidly and should be followed especially closely.

Uncomplicated *P. falciparum* malaria

Selection of an appropriate treatment for uncomplicated *P. falciparum* malaria is dependent on drug availability, resistance patterns, and individual patient-specific factors. When possible, uncomplicated *P. falciparum* malaria should be treated with a combination of two agents to inhibit the development of further antimalarial resistance. Chloroquine is the drug of choice for patients where chloroquine-sensitive *P. falciparum* can reliably be predicted based on geographic resistance patterns. For chloroquine-resistant *P. falciparum* malaria first-line treatment consists of one of the following agents: artemisinin derivative combinations, atovaquone/proguanil, quinine (in combination with doxycycline or clindamycin), or mefloquine (in combination with artesunate or doxycycline).

The WHO recommends artemisinin combination therapies (ACTs) as the first-line treatment of uncomplicated falciparum malaria as they are potent against all developmental stages of the asexual forms of malaria, resulting in the most rapid clearance time relative to other agents (WHO 2010).

Uncomplicated non-falciparum malaria

The treatment of choice for the erythrocytic forms in uncomplicated non-falciparum malaria is chloroquine as it is well tolerated and highly effective. There are small pockets of chloroquine-resistant *P. vivax* that can be treated with mefloquine, atovaquone/proguanil, or quinine in combination with doxycycline or clindamycin.

In order to prevent relapse of *P. vivax* or *P. ovale* infections, treatment directed at the hypnozoites should be considered (WHO 2010). The drug of choice for the clearance of presumed hypnozoites is primaquine. Primaquine can cause severe and potentially fatal haemolysis in individuals with G6PD deficiency. Patients should be screened for G6PD deficiency prior to administration of primaquine. Patients that have G6PD deficiency should be educated about the possibility of relapsing infection. Primaquine is contraindicated in pregnancy.

Complicated and severe malaria

Treatment of severe malaria typically requires hospitalization for high-level supportive care and the prompt administration of parenteral antimalarials (WHO 2010). There are two major classes of drugs available for parenteral treatment of severe malaria, the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether, and artemotil). Intravenous artesunate is the preferred treatment of children, adults, and pregnant women in the second and third trimesters with severe malaria (in areas where artesunate is of reliable quality and is immediately available). Otherwise, intravenous quinine (in combination with doxycycline or clindamycin) is the regimen of choice.

Burden of malaria

The burden of malaria is staggering, exacting an enormous toll in morbidity, mortality, and disability as well as resulting in

Table 8.15.3 Estimates of the global burden of malaria. Morbidity, mortality, disability, and economic cost

Morbidity cases in millions	Mortality deaths in thousands	Years lived with disability in millions	Annual economic cost in US\$
451 (349–552) (Hay et al. 2007)	1238 (929–1685) (Murray et al. 2012)	4 (Vos et al. 2012)	12 billion (Gallup and Sachs 2001)
219 (154–289) (WHO 2012a)	660 (490–836) (WHO 2012a)		

significant economic costs and impeding development (Bremar et al. 2003) (Table 8.15.3). While important progress has been made over the past decade in the control of malaria, the toll continues to be devastating. However, obtaining accurate data and determining the precise impact of malaria is difficult (Bremar and Holloway 2007). Many resource-poor, malaria-impacted countries have health infrastructures that are not highly developed and lack adequate surveillance systems. In addition, the symptoms of malaria are similar to other common infections and confirmation of malaria is not routinely performed. As a result, estimates of the burden of malaria vary considerably and disagreements about these estimates have generated considerable debate. Ultimately, while data are imperfect and estimates may differ substantially, they are uniformly high and there is consensus that malaria is a global public health problem of enormous proportion.

Morbidity

Hay and colleagues with the Malaria Atlas Project estimated that there were 451 million (range 349–552) clinical cases of *P. falciparum* malaria alone for 2007 (Hay et al. 2007) (Table 8.15.2). Almost all of this burden of morbidity occurred in areas of stable transmission. More than half of all estimated *P. falciparum* clinical cases occurred in India, Nigeria, the Democratic Republic of the Congo, and Myanmar, where 1.4 billion people are at risk. Fig. 8.15.2 from the Malaria Atlas Project (n.d.) provides a map of the global distribution of *P. falciparum*.

In contrast to the estimate of the Malaria Atlas Project group, the WHO estimated 219 million cases (range 154–289 million) of total malaria in 2010 with 80 per cent occurring in sub-Saharan Africa and 90 per cent attributed to *P. falciparum* (WHO 2012a). As a further example of the difficulty in defining the impact of malaria, wide discrepancies appear in Indonesia, where the WHO estimated approximately 2 million cases of malaria per year, with several thousand deaths. However, the Malaria Atlas Project estimated 12 million cases of *P. falciparum* alone in 2009 (Elyazar et al. 2011), and data indicate that *P. vivax* represents nearly half of malaria cases in cross-sectional surveys (Gething et al. 2012). The Central Bureau of Statistics for Indonesia conducted national household health surveys in 1995 and 2001, and each estimated 15–30 million clinical cases of malaria, causing 30,000–38,000 deaths (Baird 2013). Additionally, Hay and colleagues estimated 102 million (95 per cent CI 31–187 million) clinical attacks caused by *P. falciparum* alone in India, whereas the WHO estimate for clinical attacks caused by any species was less than one-third the lower limit of that confidence interval (Gething et al. 2012).

While less attention has been focused on the other major malaria species, *P. vivax*, recent data indicate that 2.85 billion people were exposed to some risk from this parasite in 2009 (WHO 2012a, 2012b). The majority of these (2.59 billion, 91 per cent) were residents of Central and South East Asia, particularly India and Myanmar.

Mortality

The WHO estimated that there were 660,000 malaria deaths (range 490,000–836,000) with 91 per cent occurring in sub-Saharan Africa in 2010 and the majority of deaths (86 per cent) in children under 5 years of age (WHO 2012a). However, Murray and colleagues from the Institute for Health Metrics and Evaluation (IHME) suggest much higher levels of mortality estimating 1,238,000 deaths representing a figure that is 578,000 deaths, or 87 per cent, higher (Murray et al. 2012). Similar to the WHO data, the vast majority of deaths (91.5 per cent) in the IHME estimates were in Africa, however the IHME estimates suggest substantially more malaria deaths (433,000) in individuals 5 years of age and older; 524,000 deaths compared with 91,000 estimated by the WHO.

Work by Dhingra and colleagues underscores the disparities in estimates of malaria mortality. Based on a verbal autopsy study of 122,000 deaths in India, the authors estimated 205,000 annual malaria-related deaths (95 per cent CI 125,000–277,000 deaths) (Dhingra et al. 2010). This was substantially higher than the estimate from the WHO of 15,000 (95 per cent CI 9600–21,000) deaths due to malaria in that country each year.

While most malaria deaths are attributed to *P. falciparum* infection, increasing evidence indicates that *P. vivax* plays a significant, yet under-appreciated, role in contributing to the burden of malaria mortality (Baird 2013). It is becoming increasingly evident that efforts to reduce the global burden of malaria must include activities and resources to target vivax malaria.

These varying estimates of morbidity and mortality underscore the difficulty in measuring the impact of malaria with certainty and argue for the critical need to invest in improved surveillance systems and more accurate data (Bremar and Holloway 2007; malERA Consultative Group on Monitoring, Evaluation, and Surveillance 2011). In light of these existing limitations and uncertainties, it is valuable to have multiple, if sometimes conflicting, estimates of the burden of malaria.

Malaria in pregnancy

Infection with *P. falciparum* in pregnancy can result in significant adverse consequences for mother and child (Nahlen et al. 2005). Malaria can cause or exacerbate maternal anaemia and this contributes to both maternal mortality and adverse birth outcomes, including fetal loss and low birth weight from prematurity and intrauterine growth retardation. The proportion of severe anaemia in pregnancy attributed to malaria in areas of stable transmission in Africa is estimated to be 26 per cent (Desai et al. 2007). The percentage of malaria-attributed maternal deaths has been estimated to range from 0.5–23 per cent in high transmission areas to 0.6–12.5 per cent in low transmission regions. The impact of low birth weight is considerable given its role as an important risk factor for neonatal and infant mortality and may also cause developmental and cognitive sequelae. In areas of Africa with high transmission,

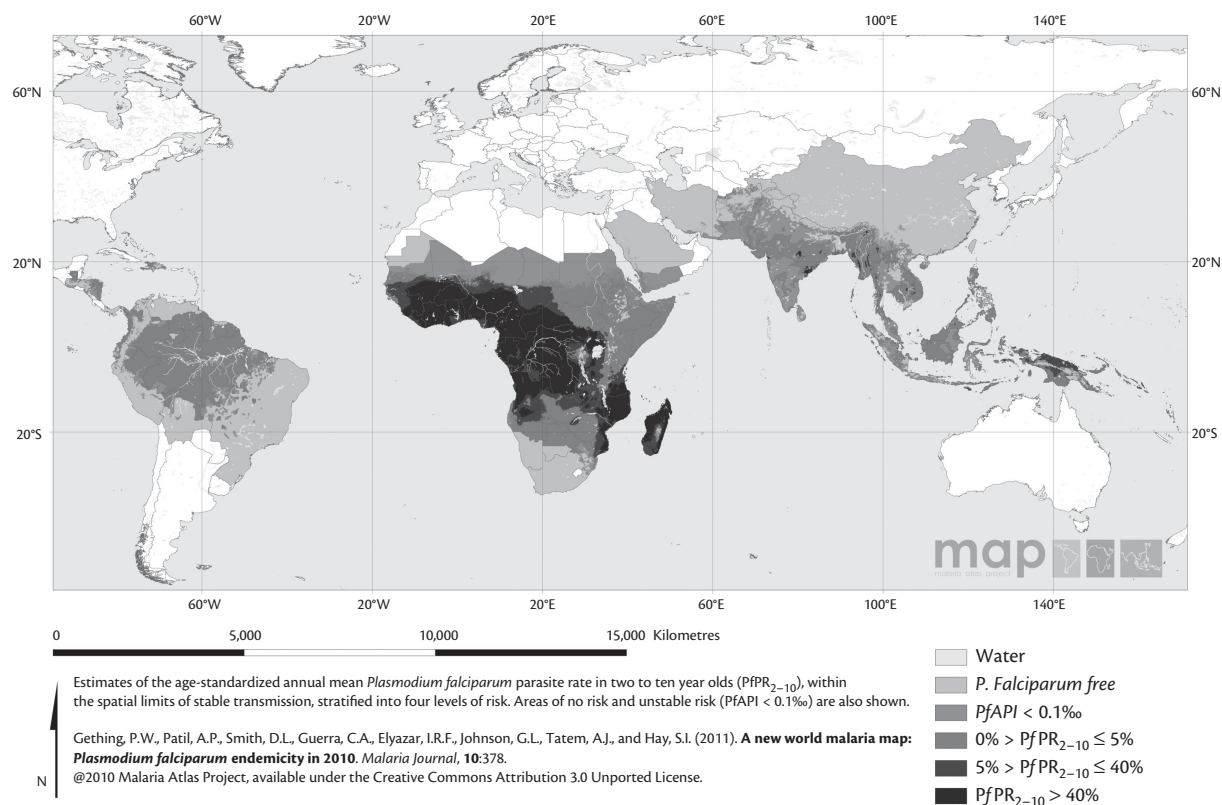

Fig. 8.15.2 The spatial distribution of *Plasmodium falciparum* malaria in 2010 stratified by endemicity class.

Reproduced from Gething, P.W. et al., A new world malaria map: *Plasmodium falciparum* endemicity in 2010, *Malaria Journal*, Volume 10, 378, Copyright © 2011 Gething et al.; licensee BioMed Central Ltd., reproduced under the Creative Commons Attribution 2.0 Generic (CC BY 2.0).

placental infection approximately doubles the risk of low birth weight with the greatest impact on primagravid women (Guyatt and Snow 2004). An estimated 12–20 per cent of low birth weight deliveries in sub-Saharan Africa are attributable to malaria resulting in an estimate of 75,000–200,000 infant deaths annually.

Exposure to malaria during pregnancy is common. Dellicour and colleagues estimated that in 2007 there were 85.3 million pregnancies in areas of *P. falciparum* transmission with 54.7 million in areas of stable transmission and 30.6 million in areas with unstable transmission (Dellicour et al. 2010). They estimated an additional 39.9 million pregnancies in temperate areas of *P. vivax* transmission only, and 53 million in areas of *P. falciparum* and *P. vivax* overlap. Maternal malaria is often common with the median prevalence of placental infection estimated at 26 per cent (range 5–52 per cent) in areas of stable transmission in Africa (Steketee et al. 2001; CDC 2012). In low transmission areas the median prevalences of peripheral and placental infection were estimated to be 13.7 per cent and 6.7 per cent in Africa and 6.2 per cent and 9.6 per cent outside Africa (Steketee et al. 2001; CDC 2012).

HIV infection, which is common in many malaria endemic regions, can modify the effect of malaria infection through increasing the risk of infection as well as resulting in higher parasite density and increased severity of disease. In pregnant women with malaria, HIV co-infection may increase the risk of anaemia and low birth weight (Dellicour et al. 2010).

Disability

The adverse and long-term neurocognitive effects of malaria-induced anaemia and cerebral malaria can be sizeable (Bremner et al. 2004). A recent estimate of years lived with disability (YLDs) indicates a high global burden for malaria totalling over 4 million YLDs in 2010, with the majority a result of malaria-induced anaemia (Vos et al. 2012). In central and western sub-Saharan regions, malaria ranked as the fourth leading cause of disability.

Economic burden

Malaria exacts considerable costs at both the individual and governmental level. Direct costs, for example, illness, treatment, and premature death, have been estimated to be at least \$12 billion per year (Gallup and Sachs 2001; CDC 2014). The economic burden is many times more than that in lost economic growth. It has been estimated that countries with intensive malaria transmission have income levels of only 33 per cent that of countries without malaria (Gallup and Sachs 2001).

Costs to individuals and their families include purchase of drugs for treating malaria at home; expenses for travel to, and treatment at, dispensaries and clinics; lost days of work; absence from school; expenses for preventive measures; and expenses for burial in case of deaths (CDC 2014). Costs to governments include maintenance of health facilities; purchase of drugs and supplies; public health interventions against malaria, such as insecticide

spraying or distribution of insecticide-treated bednets; lost days of work with resulting loss of income; and lost opportunities for joint economic ventures and tourism.

Travel-related disease

Travel-associated malaria, including fatal infections, in people from non-endemic areas is routinely reported (Dorsey et al. 2000; Mali et al. 2012). For example, the CDC annually reports approximately 1500 cases of malaria and six deaths in US residents who have acquired infection during travel to areas of malaria risk.

Prevention and control of malaria

Over the past decade there has been renewed momentum with significant resources provided from the Global Fund for HIV, Malaria and Tuberculosis and the Bill & Melinda Gates Foundation. This has led to considerable progress towards reducing the overwhelming burden of malaria, including substantial declines in mortality (CDC 2012a). However, the gains have been uneven (O'Meara et al. 2010) and must be viewed with caution given inadequate surveillance and suboptimal data. Moreover, current control approaches should be approached within the context of the previous major global effort to eradicate malaria that was aggressively and optimistically pursued in the period from 1955 to 1969 (Najera et al. 2011). While the initiative achieved important successes, including elimination of malaria in some countries and significant reduction in other areas such as India and Sri Lanka, many regions realized negligible progress. Unfortunately, a convergence of factors, including emergence of chloroquine resistance, vector resistance to insecticides, difficulties of sustaining funding, conflicts, and population movements, coupled with inadequate community participation and operational issues, resulted in lost momentum with a subsequent major recrudescence of the disease. The lessons of this key effort must be appreciated and understood if lasting malaria control is to be realized. Ultimately, in areas of significant malaria transmission, integrated and sustained approaches with commitments for adequate funding will be necessary.

The goals of reducing the impact of malaria can range from control, which targets reduction of the impact of malaria, to elimination, an approach that seeks to completely remove the disease from areas, to the lofty notion of total global eradication. There is continuing debate among acknowledged experts on the best anti-malaria strategy to pursue and any such Herculean effort benefits from the involvement of both pragmatists and idealists.

The epidemiology of malaria is exceedingly complex, formed by the interaction of agent, vector, host, and environment as well as political and socioeconomic factors. As a result, in most endemic areas malaria control requires knowledge of the local epidemiology and biology. Current control strategies can incorporate a broad array of approaches that include insecticide-treated nets (ITNs), indoor residual spraying (IRS), source reduction that targets mosquito breeding areas, area application of insecticide, intermittent preventive treatment (IPT) of pregnant women, children, and infants, identifying and treating cases, personal protective measures, and education.

Vector control

Control of anopheline vectors is a key component of efforts to reduce the burden of malaria and there are a number of effective approaches available.

Insecticide-treated nets

ITNs that are impregnated with pyrethroid preparations (typically deltamethrin or permethrin) provide a physical barrier and repellent for mosquito protection and also act to reduce vector longevity and vector populations. Studies have demonstrated that ITNs result in declines in mosquito populations and reduced burden of malaria. ITNs lowered the risk of childhood mortality by 17 per cent compared to no nets and 23 per cent to untreated nets. In areas of stable malaria, ITNs reduced the incidence of uncomplicated malarial episodes by 50 per cent compared to no nets and 39 per cent compared to untreated nets (Lengeler 2004). The benefits for preventing malaria in pregnancy have also been established. In Africa, ITNs reduced placental malaria and low birthweight by over 20 per cent and fetal loss in the first to fourth pregnancy by over 30 per cent (Gamble et al. 2006). Moreover, when ITN coverage is sufficiently high, indirect benefits can be observed for others in the community not using nets.

Historically, ITNs required retreatment at 6–12-month periods, but compliance with retreatment is low. However, newer, long-lasting insecticidal nets (LLINs) with insecticide incorporated into the fabric of the netting provide residual of 3–5 years' duration. While costlier to produce, these nets overcome the need to repeatedly retreat and are increasingly available. Barriers to the use of ITNs include discomfort, primarily from heat, cost, and availability (Pulford et al. 2011).

Indoor residual spraying

IRS is an effective means of vector control for mosquitoes and was an important component of the WHO's Global Malaria Eradication Programme from 1955 to 1969. Residual insecticide with prolonged residual activity is applied to interior walls and roofs of dwellings. Given that many of the major malaria vectors, such as *An. gambiae* in Africa, feed at night and exhibit indoor resting (endophilic) and indoor feeding (endophagic) behaviour, IRS has demonstrated considerable success. The approach has been responsible for major effects in the control and elimination of malaria including past successes in areas of Asia, Russia, Europe, Latin America, and parts of Africa (Pluess et al. 2010). A recent report by Kigozi and colleagues (2012) documented reductions in malaria morbidity in an area of high transmission intensity. IRS products include pyrethroid-class compounds, organophosphates, and carbamates. Although previously abandoned as a result of environmental concerns, the organochlorine pesticide DDT has been increasingly used in recent years and is viewed as a valuable product due to its long residual (Raghavendra et al. 2011). Effective use of IRS requires knowledge of local vector behaviour and possible resistance patterns, cooperation and acceptance by residents to ensure adequate coverage, and effective logistics. Most currently applied insecticides are pyrethroids, which have low mammalian toxicity, and DDT.

Source reduction/environmental management

Source reduction involves the elimination of water sources that serve as breeding sites for mosquitoes (Keiser et al. 2005). This can involve draining or filling in of standing water, swamps, or marsh areas, emptying or covering containers such as pots, cans, or rain barrels that can hold water and serve as sites for breeding, and intermittent irrigation. Source reduction played a key role in the control of malaria in the Panama Canal Zone, peninsular Malaysia,

and the Indonesian archipelago (Keiser et al. 2005). Such efforts can be very resource intensive and the widely dispersed nature of water sources, the difficulty in identifying all water sources, and determining where and when smaller water sources will be established, make the approach challenging. Moreover, many anopheline mosquitoes are opportunistic breeders that favour small streams and rivulets and the capacity of major vectors such as *An. gambiae* to breed in small temporary pools of water prevent the wide application of this technique (Shiff 2012).

Other means of targeting the aquatic larval stage of mosquitoes include applying oils to the water surface which prevents larvae and pupae from obtaining air. Most oils currently used for such purposes are biodegradable (CDC 2012).

Biological control

Toxins from *Bacillus thuringiensis* var. israelensis (BTI) and insect growth regulators such as methoprene can also be applied to water sources for larval control. The use of BTI has demonstrated recent success against malaria vectors and may prove useful in integrated approaches to vector management (Tiwari et al. 2011).

Bacteria, such as *Wolbachia*, are known to make vectors refractory to a variety of human pathogens. Bian and colleagues recently reported the establishment of a stable *Wolbachia* infection in an important malaria vector, *Anopheles stephensi*, that conferred resistance to *P. falciparum* (Bian et al. 2013). In addition, an *Enterobacter* species has been identified that inhibits development of the malaria parasite in *An. gambiae* (Cirimotich et al. 2011).

Biological controls such as the mosquito fish (e.g. *Gambusia affinis*), fungi (e.g. *Laegenidium giganteum*), and parasitic nematodes (e.g. *Romanomermis culicivoras*) have not been widely employed (CDC 2012).

Fogging or area spraying of insecticides

More widespread application of insecticides is primarily used in emergency situations such as epidemics and targets adult mosquitoes. Insecticide must be repeatedly applied and timed appropriately during peak periods of adult activity since it may be difficult for the insecticide to reach areas where mosquitoes are resting (CDC 2012).

Release of sterile male mosquitoes

Introducing sterile male mosquitoes has been successful in small-scale studies; however, the large numbers necessary limits applicability to most areas (Munhenga et al. 2011).

Genetic modification of malaria vectors

The use of genetic modification to develop mosquitoes that are refractory to malaria infection is an appealing concept. Such modified mosquitoes must out-compete native species to enable the resistance gene to become established (Marshall and Taylor 2009). Advances in sequencing of vector and *Plasmodium* genomes will likely provide additional insights for the development of additional approaches to malaria control (Tymoshenko et al. 2013).

Intermittent preventive therapy in pregnancy

For pregnant women who reside in malaria endemic regions, intermittent preventive therapy during pregnancy (IPTp) with sulphadoxine/pyrimethamine (SP) at scheduled antenatal care visits can reduce maternal and neonatal morbidity and mortality (Rogerson et al. 2000). Each dose suppresses or clears any existing asymptomatic infections from the placenta and provides up to

6 weeks of post-treatment prophylaxis. Among Malawian women delivering in a large urban hospital, SP prescription was associated with a decrease in placental malaria prevalence (from 31.9 per cent with no SP prescription to 22.8 per cent with two or more doses of SP), decreased prevalence of low birth weight (from 23 per cent in women not receiving SP to 10.3 per cent in women given two or more doses), and resulted in higher maternal haemoglobin concentrations (Rogerson et al. 2000). Three doses of IPTp during the second and third trimesters of pregnancy are superior to two doses of IPTp (Kayentao et al. 2013).

Intermittent preventive therapy in children

Intermittent preventive therapy in children (IPTc) is an approach used in areas of seasonal malaria transmission, such as the Sahel, where the primary burden is in older children rather than infants. IPT is administered several times, typically monthly, during the seasonal occurrence of malaria. A systematic review of seven controlled studies found a protective efficacy of 82 per cent (95 per cent CI 75–87 per cent) and reduction of all-cause mortality across 12 studies (seven controlled, five non-controlled) of 57 per cent (95 per cent CI 24–76 per cent) (Wilson and IPTc Taskforce 2011).

Intermittent preventive therapy in infants

In a review of data from six double-blind, randomized, placebo-controlled trials that assessed the efficacy of intermittent preventive therapy in infants (IPTi) with SP IPTi was found to have a protective efficacy of 30.3 per cent (95 per cent CI 19.8–39.4, $p < 0.0001$) against clinical malaria, 21.3 per cent (8.2–32.5) against the risk of anaemia, 38.1 per cent (12.5–56.2) against hospital admissions associated with malaria parasitaemia, and 22.9 per cent (10.0–34.0) against all-cause hospital admissions. No difference in mortality was demonstrated (Aponte et al. 2009).

Personal protection measures

Personal protection measures such as the use of insect repellents such as DEET and wearing long trousers, long-sleeved shirts, and light-coloured clothes can reduce mosquito exposure. Repellents may be particularly effective in areas where malaria vectors feed outdoors or in the early evening when residents may not be using ITNs (Rowland et al. 2004).

Housing

Well-constructed housing with screens provides effective protection in areas where malaria vectors bite indoors. Improved housing likely played an important role in the elimination of malaria from the United States and Europe (Harrison 1978).

Education

In a controlled study, Ayi and colleagues reported that participatory health education intervention in Ghana contributed to the decreased malaria prevalence from 30.9 per cent to 10.3 per cent among children and increased the adult utilization of bednets with insecticide from 21.5 per cent to 50.0 per cent (Ayi et al. 2010). Routine malaria education efforts may offer sustained benefits.

Prevention of malaria in the traveller

Malaria is an important cause of fever and serious illness in travellers (Mali et al. 2012). Fever in the returned traveller should be

considered malaria until proven otherwise. Approximately one in three returned international travellers presenting to a specialized travel or tropical medicine clinic, with a systemic febrile illness, has malaria (Wilson et al. 2007). Prevention of malaria in the traveller can be accomplished via personal protective measures for mosquito bite prevention and the compliant use of an effective antimalarial chemoprophylactic agent. Most travellers who develop malaria do so because they do not adhere to an effective chemoprophylactic drug regimen; however, travellers who do adhere to an effective drug regimen can still develop malaria. Fatalities may be a result of delay in seeking medical treatment, failure to obtain an adequate travel history, delayed diagnosis, laboratory error, late initiation of treatment, and/or inappropriate therapy (Dorsey et al. 2000).

Selection of an effective chemoprophylactic drug regimen is based on assessment of malaria risk based on an individual's travel itinerary and resistance patterns, and based on the individual's medical history and preferences. The agents most commonly used for chemoprophylaxis are atovaquone/proguanil, mefloquine, doxycycline, and chloroquine. These agents are effective against the erythrocytic stages of the parasite life cycle.

For travellers to *P. vivax* and *P. ovale* endemic regions, terminal prophylaxis with primaquine directed against the liver hypnozoites should be considered at the end of travel. Primaquine can cause severe or fatal haemolysis in individuals with G6PD deficiency. G6PD deficiency must be ruled out with laboratory testing prior to administration.

Vaccine

Development of an effective malaria vaccine would be a major and important milestone in malaria control. Several approaches including subunit vaccines, whole irradiated sporozoite preparations, and transmission-blocking methods have been proposed. However, despite considerable hope, aggressive efforts, and substantial economic investment to develop an effective malaria vaccine, success has been elusive (Graves and Gelband 2006; RTS,S Clinical Trials Partnership 2012; Bejon et al. 2013). Most vaccine efficacy studies have demonstrated at best only modest protection from infection. In a recent pooled analysis of the results of phase 2 data for the most advanced candidate malaria vaccine (RTS,S/AS01 or AS02) Bejon and colleagues reported an overall vaccine efficacy of 36 per cent (95 per cent CI 24–45 per cent) that was lowest, 4 per cent (95 per cent CI –10 to 22 per cent) in high transmission areas. Moreover, no protection was observed after 3 years (0 per cent, 95 per cent CI –38 to 38 per cent). Preliminary data from the phase 3 trial have estimated modest vaccine efficacy, however the full data from this ongoing trial are not expected until 2015. A better understanding of the immunological mechanisms of malaria and second-generation vaccines may be needed before a vaccine can be effectively integrated into control efforts.

Treatment

Treatment, which can serve to reduce the reservoir of people infected with malaria, and the period of infectivity, has already been addressed in this chapter. However it should be recognized that antimalarial therapy is not directly active against gametocytes.

Challenges to malaria prevention and control

Inadequate surveillance

Current malaria surveillance activities are woefully deficient (Bremner and Holloway 2007). Effective surveillance and accurate data are essential to efforts to reduce the burden of malaria. Successful targeting of interventions and pursuit of reasonable strategies for control of malaria are not possible without a clear understanding of the prevalence and incidence of malaria and where it is occurring. Importantly, surveillance also provides information that enables an evaluation of the effectiveness of ongoing interventions and enables redirecting of resources. For these reasons, strong commitments to better data and significant improvements in surveillance systems should be a priority.

Funding

Ultimately sufficient financial support may be the most important factor in the success of lasting reductions of the burden of malaria. Resource constraints have been blamed as the primary reason for the failure of the previous major mobilization against malaria (Cohen et al. 2012). Adequate funding is also key to capacity development (Greenwood et al. 2012). Despite a massive influx of resources over the past decade for malaria, increasing from about \$100 million in 2003 to \$1.71 billion in 2010, there has been a plateauing of funding (\$1.66 billion in 2011 and \$1.84 billion in 2012). Moreover, competing priorities at the global and national levels threaten continued allocation of funds. Ultimately, static funding, while admittedly considerable, may not be sufficient to realize permanent decreases in the burden of malaria.

Operational challenges

It has been suggested that the previous global effort to eradicate malaria failed, in part, as a result of requiring scientists to become field managers (Shiff 2002). Even the best tools and the most noble of goals will be destined to fail without effective implementation. Such implementation requires strong and sustained operational direction and long-term commitments with integration into national health infrastructure and participation of communities (malERA Consultative Group on Health Systems and Operational Research 2011; Najera et al. 2011).

Insecticide resistance

Sixty-four malaria-endemic countries are currently reporting mosquito resistance to at least one insecticide used for malaria control including pyrethroids (Ranson et al. 2011). In addition, selective pressure, induced by insecticides, has resulted in modified vector behaviour and emergence of new vectors being observed (Asidi et al. 2012).

Repurposing insecticides currently used for agriculture and reformulating current preparations may offer tools to combat vector resistance. Using combinations of insecticides, rotating different preparations and mosaic application are additional approaches to resistance management (malERA Consultative Group on Vector Control 2011; Alonso et al. 2013).

Drug resistance

Given the existing widespread resistance of *P. falciparum* to chloroquine and SP, the availability of highly effective artemisinin-based

compounds has provided a major tool for reducing the burden of malaria. Subsidies (termed the Affordable Medicines Facility) for artemisinin-based combination therapy have led to increased availability and reduced costs (Tougheret et al. 2012). However, reports of emerging artemisinin resistance on the Cambodia–Thailand and Thailand–Myanmar borders are cause for concern (Fairhurst et al. 2012). Resistance is driven by poor quality and counterfeit medication as well as the use of artemisinin monotherapy. A recent published report indicates that up to 36 per cent of antimalarial drugs collected in southeast Asia were falsified, whereas in sub-Saharan Africa, a third failed chemical assay analysis (Nayyar et al. 2012).

Resistance to SP also threatens to compromise its use for intermittent preventive therapy in pregnancy and for children and infants. Combination therapy using azithromycin and chloroquine may offer an alternative that can provide protection against sexually transmitted infections as well (Chico et al. 2011).

Testing of currently available drugs for antimalarial activity is one of the key approaches to combating drug resistance and can accelerate production of new therapies as well as reduce costs. Itraconazole, posaconazole, and atorvastatin are among such commercially available drugs that have demonstrated activity against malaria. In addition, chemical modification of available antimalarials and hybridization of existing drugs to improve their effectiveness and high-throughput screening and molecular modelling are being employed in attempts to identify new potentially effective therapies (Aguiar et al. 2012).

Summary

Malaria is a preventable disease but remains one of the world's great scourges. However, renewed resources and international resolve have resulted in progress towards reducing the burden of malaria and led to cautious optimism about the future elimination of this disease. Given the availability of proven methods for malaria control, as well as the promise offered by innovative approaches for vector control, improved diagnostics and therapy, and the potential for vaccine development, such cautious optimism is not unwarranted. The science of malaria may be reaching the point of making elimination, and even eradication, possible.

However, science alone will be insufficient to conquer malaria and both significant resources and unflagging resolve, at the international and local level, will be necessary to consolidate the recent gains made and to make additional progress. Yet, both resources and resolve are not unlimited, and areas impacted by malaria have many pressing problems such as HIV/AIDS, tuberculosis, food shortages, poverty, pollution, and other critical issues (Lozano et al. 2012). Reducing the burden of malaria will have to be part of a broader dialogue to determine priorities (De Cock et al. 2013).

Hepatitis B

Aetiological agent

Hepatitis B virus (HBV) is a double-stranded, enveloped virus of the *Hepadnaviridae* family. The *Hepadna* virus family has the smallest genome of all replication competent animal DNA viruses. The single most important member of the family is HBV.

The hepatitis B virion consists of a surface and a core, which contains a DNA polymerase and the e antigen. The DNA structure is double-stranded and circular with four major genes: the S (surface), the C (core), the P (polymerase), and the X (transcriptional transactivating). The S gene consists of three regions—S, pre-S1, and pre-S2—that encode the envelope protein (HBsAg). HBsAg is a lipoprotein of the viral envelope that circulates in the blood as spherical and tubular particles. The C gene is divided into two regions, the pre-core and the core, and codes for two different proteins, the core antigen (HBcAg) and the e antigen (HBeAg).

HBV strains are classified into eight genotypes designated A to H, most of which have a characteristic geographical distribution (Cao 2009; Tanwar and Dusheiko 2012). More recently, two additional genotypes, I and J, have been described in Asia (Tatematsu et al. 2009; Tran et al. 2008). Except for these newly identified genotypes, the geographic distributions of HBV genotypes are well characterized. Genotype A is highly prevalent in sub-Saharan Africa, Northern Europe, and Western Africa. Genotypes B and C are the major variants in South and South East Asia and the Pacific region. Genotype D is prevalent in Africa, Europe, the Mediterranean region and India. Genotype E is restricted to West Africa. Genotype F is found in Central and South America. Genotype G has been reported in France, Germany, and the United States and genotype H is found in Central America (Kurbanov et al. 2010; Lin and Kao 2011).

The genotypes A, B, C, D, and F have further been subdivided in up to four major subgenotypes and several minor genotypes, now identified by Arabic numerals.

The HBV infection is controlled by cellular and humoral immune responses. It can be tracked through serological detection of the virus particles or the antibodies raised by the immune system to target the virus. The presence of hepatitis B surface

and/or hepatitis B core antibodies (anti-HBs and anti-HBc) in the absence of HBsAg is generally taken to indicate resolution of infection and provides evidence of previous HBV infection. Persistence of HBV infection (chronic carrier) is diagnosed by the detection of HBsAg in the blood for at least 6 months or through detection of HBV-DNA even in the absence of detectable HBsAg in patients with occult HBV infection. HBeAg is an alternatively processed protein of the pre-core gene that is only synthesized under conditions of high viral replication. HBV-DNA is used as an indicator for viral replication expressed as IU/mL or copies/mL (the value of copies/mL is approximately 5 times more than the IU units). There is a clear association between serum HBV-DNA levels (viral load) and prognosis: the cumulative incidence of cirrhosis or hepatocellular carcinoma (HCC) being 4.5 and 1.3 per cent, respectively, in persons with DNA levels less than 300 copies/mL (corresponding to 50 IU/mL), while it is 36.2 and 14.9 per cent, respectively, in persons with DNA levels of more than or equal to 10^6 copies/mL (corresponding to 2×10^5 IU/mL). This is the rationale for treating patients with high levels of HBV DNA (Chen et al. 2006; Lok and McMahon 2007).

Epidemiology

Globally, hepatitis B is one of the most common infectious diseases. Estimates indicate that about 2 billion people (i.e. about 30 per cent of the world population) have been infected with HBV worldwide, with over 240 million people being chronic carriers (World Health Organization (WHO) 2012). On the basis of sero-epidemiological surveys, the WHO has classified countries into three levels of endemicity according to the prevalence of chronic HBsAg carriage (Fig. 8.16.1): high (8 per cent or greater), intermediate (2–7 per cent), and low (less than 2 per cent) (WHO 2004).

HBV is transmitted by either percutaneous or mucous membrane contact with infected blood or other body fluid. The virus is found in highest concentrations in blood and serous exudates (up to 10^9 virions/mL). The primary routes of transmission are perinatal, early childhood exposure (often called horizontal transmission), sexual contact, and percutaneous exposure to blood or infectious body fluids (i.e. injections, needle stick, blood transfusion, tattoos).

Hepatitis B, countries or areas at risk

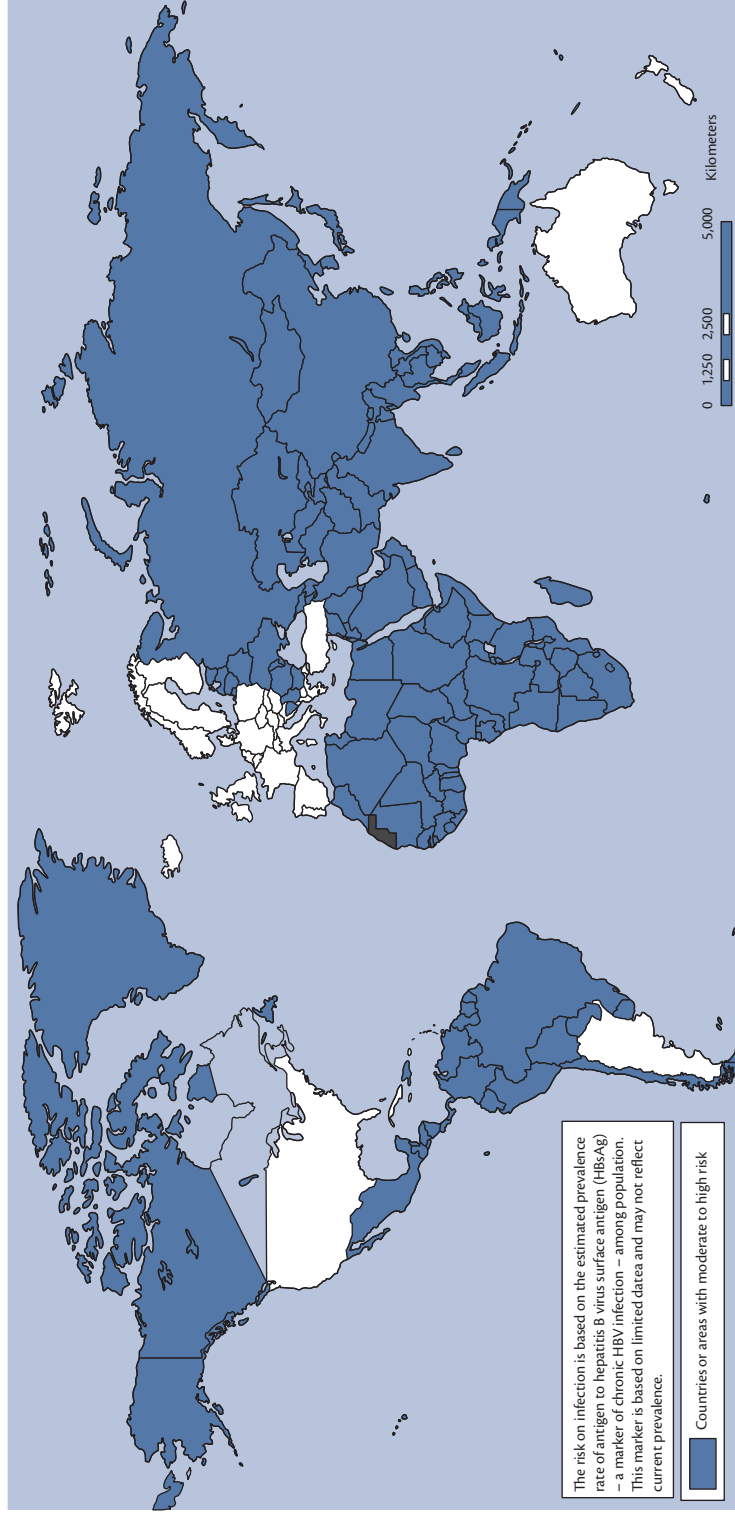

Fig. 8.16.1 Map representing all countries with moderate (2–8% HBsAg positivity) and high (8% HBsAg positivity) endemicity for hepatitis B.

Reproduced with permission from World Health Organization, *Hepatitis B, Countries or Areas at Risk*, Copyright © WHO 2012, available from http://gamapserver.who.int/mapLibrary/Files/Maps/Global_HepB_ITHRiskMap.png.

Most perinatal infections occur among infants of pregnant women with chronic HBV infection. The likelihood of an infant developing chronic HBV infection is 70–90 per cent for those born to HBeAg-positive mothers (corresponding to high titres of HBV DNA) and less than 15 per cent for those born to HBeAg-negative mothers. Most early childhood infections occur in households of persons with chronic HBV infection. The most probable mechanism involves unapparent percutaneous or permucosal contact with infectious body fluids (e.g. bites, breaks in the skin, dermatological lesions, skin ulcers). Sexual transmission has been estimated to account for 50 per cent of new infections among adults in industrialized countries. The most common risk factors include multiple sex partners and history of a sexually transmitted infection. Finally, unsafe injections and other unsafe percutaneous or permucosal procedures (such as cocaine snorting) are a major source of blood-borne pathogen transmission (HBV, hepatitis C virus (HCV), human immunodeficiency virus (HIV)) in many countries. The risk of HBV infection from needle stick exposure to HBsAg-positive blood is approximately 30 per cent and worldwide unsafe injection practices account for approximately 8–16 million HBV infections each year.

In areas of high endemicity, the lifetime risk of HBV infection is more than 60 per cent, and most infections occur during the perinatal period (transmission from mother to child) or during early childhood. In areas of intermediate endemicity, the lifetime risk of HBV infection varies between 20 and 60 per cent, and infections occur in all age groups through the four modes of transmission, but primarily in infants and children. In areas of low endemicity, infection occurs primarily in adult life by sexual or parenteral transmission (e.g. through drug use). Although acute infection is more often clinically expressed in adults, infections in infants and pre-school age children are at greatest risk of becoming chronic, thereby increasing the risk of cirrhosis and primary HCC later in life. The precise mechanism by which carrier rates are influenced by age of infection is unknown but probably relates to the effect of age on the immune system's ability to clear and eliminate the infection.

Approximately 75 per cent of the world's chronic hepatitis B carriers live in Asian countries. China ranks highest, with 100 million hepatitis B carriers, and India the second highest, with a carrier pool of 35 million (Tandon and Tandon 1997). Importantly, chronic carriers of HBV are not only at risk of developing long-term progression of the infection but also represent a significant source and reservoir of infection to others.

A model developed in 2005 estimated that in the year 2000, 620,000 persons died worldwide from HBV-related causes: 580,000 (94 per cent) from chronic infection-related cirrhosis and HCC and 40,000 (6 per cent) from acute HBV infection. Infections acquired during the perinatal period, in early childhood (<5 years old), and at 5 years of age and older accounted for 21 per cent, 48 per cent, and 31 per cent of deaths, respectively (Goldstein et al. 2005).

Besides the age at which the infection is acquired, some of the variation in outcome of HBV infection may be related to the genetic heterogeneity of the virus. Progression to chronic infection appears to occur more frequently following acute infection with genotypes A and D than with the other genotypes (Tanwar and Dusheiko 2012). Chronic infection with genotype A and B appears to have a better prognosis than genotype C and D. Pre-core mutant infection is also most common in genotypes B, C, and D,

which explains why pre-core mutant infection is more common in Asia and Southern Europe.

Clinical manifestations

Acute hepatitis B has a long incubation period ranging from 15 to 180 days (90 days on average) during which the individual is infectious. Individual responses to the infection vary greatly. One-third of the individuals have subclinical infection; one-third experience a mild 'flu-like' illness without jaundice; and the remaining one-third develop jaundice with dark urine, extreme fatigue, anorexia, and abdominal pain. Jaundice usually peaks within 1–2 weeks and then gradually subsides. About 95 per cent of adults recover completely, although this may require 6 months or more with persistent tiredness. A small proportion (1 per cent) of adults develop fulminant hepatitis, an exceptionally severe form of the disease which can be fatal requiring in two-thirds of cases an emergency liver transplant (Sherlock 1993). About 5–10 per cent of acutely infected adults and 50–90 per cent of newborns will become chronically infected and remain infectious.

The natural history of chronic HBV infection can vary dramatically between individuals. Risk factors which affect progression to chronic hepatitis, cirrhosis, and HCC include male gender, viral load, elevated alanine aminotransferase (ALT), genotype, and degree of fibrosis on liver biopsy. Some patients with persistent HBV infection will develop the condition commonly referred to as a chronic carrier state (HBsAg positivity in two occasions 6 months apart). These patients, who are still potentially infectious, have no symptoms and no abnormalities on laboratory testing. Some individuals with chronic HBV infection will have clinically insignificant or minimal liver disease and never develop complications. Others will have clinically apparent chronic hepatitis. Chronic infection with HBV can be either 'replicative' or 'non-replicative'. The 'replicative' phase or immune tolerance phase, characterized by positive HBeAg and high viral load (> 2 IU/mL, in particular if > 20 IU/mL), is often present in newborns and children of HBsAg-positive mothers. In 'non-replicative' infection, the rate of viral replication in the liver is low, serum HBV DNA concentration is generally low, and HBeAg is not detected. In these inactive HBsAg carriers, reactivation can occur either spontaneously or by immune suppression. Patients with chronic HBV and replicative infection generally have a worse prognosis and a greater chance of developing cirrhosis and/or HCC (Chen et al. 2006). In rare strains of HBV with mutations in the pre-core gene, replicative infection can occur in the absence of detectable serum HBeAg.

Treatment

HBV treatment depends on the phase of chronic HBV infection. Viral replication is necessary to cause liver injury, but the host immune system activation plays the main role in causing hepatocellular damage. As HBV is not directly cytopathic, if the patient is immunotolerant, he may present high viral load without necro-inflammation. When immunotolerance is lost, the host immune system causes liver injury. This is the immune clearance phase, when ALT increases and necro-inflammation and, consequently, liver fibrosis is found in the liver. A long-term immune clearance phase causes more fibrosis and compromises liver function. If the host immune system imposes immune control against the virus, viral replication dramatically drops down and liver damage almost disappears, but the HBV cannot be eliminated

because its DNA is already integrated in the host cells. This is the inactive phase, which can reverse to the immunoclearance phase in case of host immune depression or viral mutations. In this case, the necro-inflammatory activity returns.

Treatment is indicated if ALT is elevated, HBV-DNA is more than 2 IU/mL (European Association for the Study of the Liver 2012) or 20 IU/mL (Lok and McMahon 2009) and if there are signs of moderate or severe liver fibrosis.

The main goal of therapy for chronic HBV infection is to significantly suppress replication of HBV, thus preventing liver disease progression to cirrhosis and its complications, and reducing secondary spread. Treatment of chronic HBV infections has some limited success. Antiviral therapy will only rarely lead to complete resolution of persistent HBV infection (negativation of HBsAg). Furthermore, residual HBV DNA in the form of intra-nuclear covalently closed circular (ccc)-DNA may still be present in patients who lost HBsAg and seroconverted to anti-HBs, a situation which leads to occult HBV infection.

In patients who are HBeAg-positive, the goal of treatment is HBeAg seroconversion with sustained suppression of HBV DNA and rarely HBsAg loss or seroconversion. In those who are HBeAg-negative, the goal of treatment is sustained suppression of HBV DNA and, consequently, reduced liver injury as measured by ALT levels as well as HBsAg loss or seroconversion (which is achieved only on rare occasions).

Recommendation for therapy is dictated by the level of HBV DNA, liver enzymes and necro-inflammatory activity in liver biopsy. More recently, non-invasive methods to define the fibrosis stage are also accepted to indicate treatment, mainly in HBeAg negative patients (European Association for the Study of the Liver 2012).

Several therapies are now licensed: nucleos(t)ide analogues and interferon-based therapy. The latter is more indicated in HBeAg positive patients, but in Europe it can also be indicated in selected cases of HBeAg negative HBV carriers. Depending on the defined outcome, approximately one-third of HBeAg patients respond to a 1-year course of α -interferon therapy, taking HBeAg/Anti-HBe seroconversion as the aim of the treatment.

Currently, interferon-based therapy appears to be superior to nucleos(t)ide analogues, due to the relatively higher rate of anti-HBe seroconversion, the limited duration of treatment as compared to nucleos(t)ide analogues, the potential, albeit rare, HBsAg loss after 1 year of therapy, the lower overall cost and the absence of resistance (Hoofnagle et al. 2007). On the other hand, interferon causes more adverse events and must be administered

subcutaneously. Because of that, many physicians and even patients do not choose interferon as the first-line treatment.

Treatment with nucleos(t)ide analogues is very effective in suppressing viral load but the end point of treatment is undetermined and long-term treatment is required, which remains costly and unavailable to the majority of those affected. Combination therapy (interferon-based and nucleos(t)ide) does not lead to a better viral response.

There are nowadays many licensed nucleos(t)ide analogues: lamivudine, telbivudine, entecavir, tenofovir, and tenofovir/entecavir. Among these, entecavir and tenofovir are usually preferred, because of the higher genetic barrier (low probability of resistance) and higher potency.

The nucleos(t)ide analogue based treatment has no time definition. In the vast majority of cases, the patient needs to be treated for a long time, but they are usually safe, without significant adverse effects.

Public health impact

HBV infection is a serious global health problem. Of the approximately 2 billion people who have been infected worldwide up to 2012, more than 240 million are chronic carriers of HBV (WHO 2012). Approximately 15–40 per cent of infected patients will develop cirrhosis, liver failure or HCC. HBV infection accounts for an estimated 600,000 deaths each year, mainly due to the consequences of chronic hepatitis, such as cirrhosis and liver cancer (Goldstein et al. 2005; Lavanchy 2004; Perz et al. 2006a). Because these complications mainly occur in adults who quite often were infected with HBV as children, most of the benefits of vaccination initiated 20 years ago have yet to be realized. Table 8.16.1 summarizes the global prevalence and mortality of HBV versus the observed prevalence and mortality of HCV and human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS). Another consequence, often underestimated, is the stigma that HBV carries to the individual, in the family setting, as well as in social and professional life.

Prevention

All major health authorities agree that the most effective approach to reducing the burden of HBV is primary prevention through universal vaccination and control of disease transmission. Interrupting the chain of infection requires knowledge of the mode of disease transmission and modification of behaviour through individual education to practice safe sex and good personal hygiene. Screening of all donated blood and maintenance

Table 8.16.1 Global disease burden for hepatitis B, hepatitis C, and HIV/AIDS

	Hepatitis B	Hepatitis C	HIV/AIDS
Global prevalence	2 billion	150 million	34 million
Chronic infection	240 million	120 million	34 million
Number of deaths per year	600,000	350,000	1.7 million

of strict aseptic techniques with invasive health treatments have reduced the likelihood of contracting HBV.

Safe and effective HBV vaccines have been available since the 1980s, and immunization with HBV vaccine remains the most effective means of preventing HBV disease and its consequences worldwide. Although the vaccine will not cure chronic hepatitis, it is 95 per cent effective in preventing chronic infections from developing, and is the first vaccine against a major human cancer.

After the development of plasma-derived vaccines (in 1982), which continue to be used mostly in the low- and middle-income countries, recombinant DNA technology has allowed the expression of HBsAg in other organisms. As a result, different manufacturers have successfully developed recombinant DNA vaccines against HBV (commercialized in 1986).

Moreover, apart from monovalent vaccines against hepatitis B, a broad range of combination vaccines that include an HBV component exist, especially for vaccination during infancy and early childhood. Most of these simultaneously immunize against tetanus, diphtheria, and pertussis (with either a whole-cell or an acellular component); they may also include antigens for vaccination against polio and/or *Haemophilus influenzae* b. For each of these combination vaccines, it has been shown that the respective components remain sufficiently immunogenic, and that the combination vaccine is safe.

More recently, the so-called third-generation hepatitis B vaccines—based on the S-, pre-S1-, and pre-S2-antigens, or using new adjuvants—have been and are being developed. These vaccines specifically aim to enhance the immune response in immunocompromised persons and non-responders (Rendi-Wagner et al. 2006; Shouval et al. 1994).

Immunization against hepatitis B requires the intramuscular administration of three doses of vaccine given at 0, 1, and 6 months. More rapid protection (i.e. for healthcare workers exposed to HBV or the susceptible sexual partner of a patient with acute hepatitis B) can be achieved through the adoption of an alternative schedule using three doses of vaccine administered at 0, 1, and 2 months followed by a booster dose given at 12 months. The extensive use of both plasma-derived and recombinant HBV vaccines since their becoming available has confirmed their safety and excellent tolerability. However, in recent years, the safety of hepatitis B vaccine has been questioned, particularly in some countries. In 1998, several case reports from France raised concern that hepatitis B vaccination may lead to new cases or relapse of multiple sclerosis (MS) or other demyelinating diseases, including Guillain-Barré syndrome; however, no causal relation has been established (Duclos 2003). Hepatitis B vaccination is not contraindicated in pregnant or lactating women.

Seroprotection against HBV infection is defined as having an anti-HBs level 10 IU/L after complete immunization (Centers for Disease Control and Prevention 1987). Reviews on the use of HBV vaccine in neonates and infants report seroprotective levels of anti-HBs antibodies at 1 month after the last vaccine dose for all schedules in 98–100 per cent of vaccinees (Venters et al. 2004). While HBV vaccines generally induce an adequate immune response in over 95 per cent of fully vaccinated healthy persons, a huge interpersonal variability has been demonstrated in the immune response. The antibody response to hepatitis B vaccine has been shown to depend on the type, dosage and schedule of vaccination used, as well as on the age, the gender, genetic factors,

co-morbidity, and the status of the immune system of the vaccinee (Hadler and Margolis 1992; Hollinger 1989). Immunodeficient patients, such as those undergoing haemodialysis or immunosuppressant therapy, require higher doses of vaccine and more injections (at months 0, 1, 2 and 6) to achieve an adequate and sustained immune response.

Follow-up studies have shown that vaccine-induced antibodies persist over periods of at least 20 years and that duration of anti-HBs positivity is related to the antibody peak level achieved after primary vaccination (Jilg et al. 1988; Leuridan and Van Damme 2011). Follow-up of successfully vaccinated people has shown that the antibody concentrations usually decline over time, but clinically significant breakthrough infections are rare. Those who have lost antibody over time after a successful vaccination usually show a rapid anamnestic response when boosted with an additional dose of vaccine given several years after the primary course of vaccination or when exposed to the HBV. This means that the immunological memory for HBsAg can outlast the anti-HBs antibody detection, providing long-term protection against acute disease and the development of the HBsAg carrier state (Banatvala and Van Damme 2003). Hence, for immunocompetent children and adults the routine administration of booster doses of vaccine does not appear necessary to sustain long-term protection (European Consensus Group 2000). Such conclusions are based on data collected during the first 10–20 years of vaccination in countries of both high and low endemicity (Kao and Chen 2005; Zanetti et al. 2005).

Since the availability of hepatitis B vaccines in industrialized countries, strategies for HBV control have stressed immunization of high-risk groups (e.g. homosexual men, healthcare workers, patients in sexually transmitted infection clinics, sex workers, drug users, people with multiple sex partners, household contacts of chronically infected persons) and the screening of pregnant women. As observed and reported in many countries, and though it is certainly desirable to immunize these persons, it is unlikely that such a programme limited to high-risk groups will control HBV infection in the community.

In 1991, the WHO called for all children to receive the HBV vaccine. Substantial progress has been made in implementing this WHO recommendation: by the end of 2012, 179 countries had implemented or were planning to implement a universal HBV immunization programme for newborns, infants, and/or adolescents. Of these, 147 (82 per cent) countries reported HBV infant vaccination coverage over 80 per cent after the third dose; these countries are mainly situated in Europe, North and South America, Northern Africa, and Australia (UNICEF and WHO 2012).

High coverage with the primary vaccine series among infants has the greatest overall impact on the prevalence of chronic HBV infection in children (WHO 2004). According to model-based predictions, universal HBV infant immunization (without administration of a birth dose of vaccine to prevent perinatal HBV infection), would prevent up to 75 per cent of global deaths from HBV-related causes, depending on the vaccination coverage for the complete series. Adding the birth dose would increase the proportion of deaths prevented up to 84 per cent (Goldstein et al. 2005).

In countries with high or intermediate disease endemicity, the most effective strategy is to incorporate the vaccine into the

routine infant immunization schedule or to start immunization at birth (< 24 hours). Countries with lower prevalence may consider immunization of children or adolescents as an addition or an alternative to infant immunization (WHO 2004, 2006).

Indeed, the effectiveness of hepatitis B newborn and infant immunization programmes has already been demonstrated in a variety of countries and settings (André and Zuckerman 1994; Lee 1997; WHO 2001). The results of effective implementation of universal hepatitis B programmes have become apparent in terms of reduction not only in the incidence of acute hepatitis B infections, but also in the carrier rate in immunized cohorts and in hepatitis-B-related mortality—two ways to measure the impact of a hepatitis B vaccination programme (Coursaget et al. 1994).

In Taiwan, the HBsAg prevalence in children under 15 years of age decreased from 9.8 per cent in 1984 to 0.7 per cent in 1999 (Chan et al. 2004). In the Gambia, childhood HBsAg prevalence decreased from 10 per cent to 0.6 per cent since the introduction of the universal infant immunization programme (Viviani et al. 1999). Data in Hawaii show a 97 per cent reduction in the prevalence of HBsAg since the start of the infant hepatitis B vaccination programme in 1991. The incidence of new acute hepatitis B infections in children and adults was reduced from 4.5/100,000 in 1990 to 0 in the period 2002–2004 (Perz et al. 2006b). In Bristol Bay, Alaska, 3.2 per cent of children were HBsAg positive before universal hepatitis B immunization; 10 years later, no child under 10 years of age was HBsAg positive (Wainwright et al. 1997). Finally, surveillance data from Italy, where a universal programme was started in 1991 in infants as well as in adolescents, have shown a clear overall decline in the incidence of acute hepatitis B cases from 11/100,000 in 1987 to 3/100,000 in 2000 (Romano et al. 2004).

Hepatitis D virus

Hepatitis D virus (HDV) is a transmissible pathogen that requires the help of a hepadnavirus like HBV for its own replication—similar to viroids or plant virus satellite RNAs. Thus, in a natural setting, HDV is only found in patients who are also infected with HBV since the HDV RNA genomes are assembled using the envelope proteins of HBV and HDV buds through the HBsAg excretory pathway.

The HDV genome is a small single-stranded RNA genome composed of approximately 1680 bases with a unique circular conformation that is replicated using a host RNA polymerase. A rolling-circle model has been developed for its RNA replication, which is unique, at least among agents that infect animals. The HDV genome contains an open reading frame translated to the small (S-HD) and large (L-HD) proteins. The L-HD amino acid sequence is identical to S-HD with the addition of a carboxy-terminal extension of 19–20 amino acids following the editing of the S-HD stop codon during the viral RNA replication cycle. The S-HD is required for viral replication and might promote RNA polymerase II elongation of nascent HDV RNA, while L-HD is essential for HDV particle assembly (Tseng and Lai 2009).

There are two types of HDV infection: co-infection and super-infection (Rizzetto and Verme 1985). HDV and HBV can infect individuals simultaneously, transmitted by the same inoculums, characterizing a co-infection. On the other hand, the HDV can infect a chronic HBV carrier, characterizing a super-infection.

A co-infection usually evolves into complete recovery, but the risk for severe acute hepatitis, even fulminant hepatitis, is higher than in the case of acute HBV mono-infection. A super-infection evolves toward chronicity in about 90 per cent of cases. Chronicity is associated with an increased risk of developing advanced chronic liver disease, early cirrhosis development, and hepatocarcinoma (Farci 2003; Smedile and Bugianesi 2005).

Eight HDV genotypes have been characterized to date on the basis of a small number of complete genome sequences with 19–38 per cent divergence at the nucleotide level of complete genomes (Hughes et al. 2011). The most frequent genotypes are: genotype I (includes the European, North American, African, and some Asian HDV isolates), genotype II (found in Japan, Taiwan, and Eastern Europe), genotype III (found exclusively in South America), genotype IV (found mainly in West-Africa) and genotype V (found in Central Africa).

The global distribution of the different genotypes of HBV and HDV is rather well known, although less is known on the types circulating among populations in remote areas and on the way the different viruses and their respective genotypes interact in multiple infected individuals. Little is also known on the viral transmission mechanisms driving the circulation of the endemic strains and epidemic outbreaks.

The prevalence of HDV infection increases in the equatorial subtropical and tropical zones, concentrating in certain population groups which are considered high endemicity models (Torres 1996). Preliminary data suggest that hepatitis delta in Brazil, endemic in the Western Amazon states, is more severe compared to other regions; however this needs further evidence (Paraná et al. 2008; Viana et al. 2005). In Western Europe, HDV is becoming rare, affecting around 5 per cent of chronic carriers (Rizzetto and Ciancio 2012).

In endemic areas, all HBV carriers should be further screened for delta hepatitis virus (which requires the availability of anti-HDV IgG and IgM serological tests).

Hepatitis C

Aetiological agent

HCV is classified in the family *Flaviviridae*. Like other flaviviruses, HCV is an enveloped RNA virus with an inner nucleoprotein core. Its envelope contains two glycoproteins, E1 and E2, which form heterodimers (to form a functional subunit) at the surface of the virion. Efforts to isolate the virus by standard immunological and virological techniques were unsuccessful and HCV was finally identified by direct cloning and sequencing of its genome. Although the virus was identified 25 years ago (in 1989) (Choo et al. 1989), its replication cycle is still not fully understood. An important feature of HCV is that the viral genome displays extensive genetic heterogeneity at the local as well as the global level. Even within a host, the HCV genome population circulates as a 'quasi-species' of closely related sequences. Worldwide, a high degree of genetic variation exists, resulting in at least six major genotypes and more than 100 distantly related subtypes (Forns and Bukh 1999). It has been reported that virus pathogenicity and sensitivity to current standards of treatment appear to vary with different subtypes (genotypes 2 and 3, responding better than genotype 1 and 4). These characteristics of HCV, much like HIV, make it a moving target for vaccine design.

Epidemiology

HCV is a major cause of acute hepatitis and chronic liver disease, including cirrhosis and HCC. Globally, an estimated 150 million persons are infected with HCV and more than 350,000 people are estimated to die from HCV-related liver diseases (Alter 2007; WHO 2012). The worldwide prevalence of HCV-infected people ranges from 1 per cent in high-income countries to around 10 per cent in low- and middle-income countries (Fig. 8.16.2). Table 8.16.1 summarizes the global prevalence and mortality of HCV versus the observed prevalence and mortality of HBV and HIV/AIDS.

The reported seroprevalence in the Nile delta ranges from 19 per cent in the 10–19-year-old age group to 60 per cent in the 30-year-old age group, and is associated with a high prevalence of liver cirrhosis in Egypt. The higher prevalence in the Nile delta is reported to be linked to parenteral anti-schistosomiasis therapy, which was carried out with inadequately sterilized injection material (Frank et al. 2000). Current estimates in the United States are that 3.9 million Americans are chronically infected with HCV, with prevalence rates as high as 8–10 per cent in African Americans. Haemodialysis patients, haemophiliacs, drug addicts, and people transfused with blood before 1990 are particularly affected by the disease. In Europe, 0.1–3.3 per cent of the population has been infected, with the highest prevalence observed in Southern Europe (Italy and Romania) (Blachier et al. 2013).

Despite infection control precautions, healthcare providers remain at risk for acquiring blood-borne viral infections due to accidental exposure. Therapeutic injections are reported as accounting for 2 million new HCV infections each year. Many of these injections are performed in less than ideal conditions, often with reuse of needles or multidose vials and mainly, but not

exclusively, in low- and middle-income countries. The residual risk of transmitting HCV through blood transfusion is very low in industrialized countries but safety of blood supply remains a major source of public concern in low- and middle-income countries.

Up to 60–70 per cent of intravenous drug users living in urban areas are seropositive for HCV antibodies. The rate of infection depends on the length of drug use, with 25 per cent of infections occurring during the first year of addiction, 50 per cent after 5 years, and up to 90 per cent after more than 5 years of intravenous drug use.

Transmission

The global epidemic of HCV infection emerged in the second half of the twentieth century and has been attributed, at least in part, to the increasing use of parenteral therapies and blood transfusion during that period. In high-income countries, the rapid improvement of healthcare conditions and the introduction of anti-HCV screening for blood donors have led to a sharp decrease in the incidence of iatrogenic HCV (Prati 2006). Injectible drug use remains the main route of transmission, accounting for nearly 90 per cent of new HCV infections. Mother-to-child transmission has been widely documented. The risk of perinatal infection in children from HCV-infected mothers ranges from 3 per cent to 10 per cent in different populations. Transmission is believed to occur *in utero*, as a consequence of a high viral load in the mother (in particular, from mothers who are HIV-co-infected) (Kato et al. 1994). There is no contraindication for infected mothers to breastfeed the newborn. Sexual transmission is thought to be relatively infrequent (2–3 per cent); as such, it is not recommended in monogamic and stable couples to use condoms. However, the

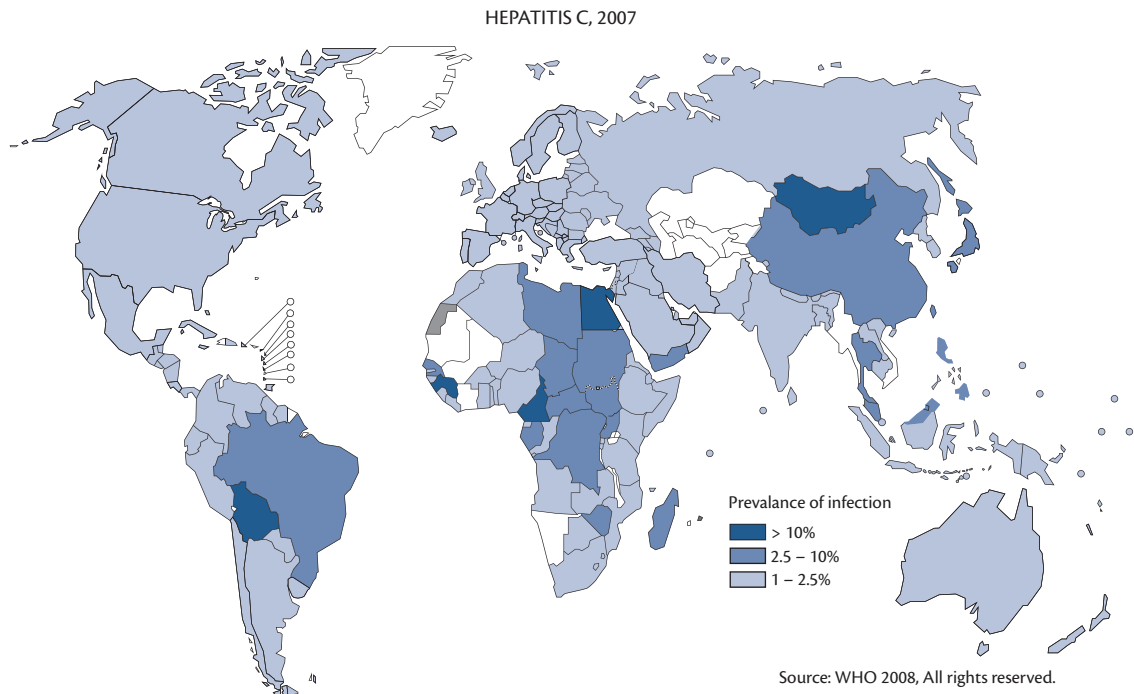

Fig. 8.16.2 Map representing countries with low (1–2.5%), moderate (2.5–10%), and high (> 10%) hepatitis C virus prevalence.

Reproduced with permission from World Health Organization, *Hepatitis C*, Copyright © WHO 2008, available from <http://www.who.int/ith/maps/hepatitisc2007.jpg>.

large reservoir of HCV carriers provides multiple opportunities for exposure to potentially infected partners. Individuals with multiple sexual partners, male homosexuals, prostitutes and their clients, patients with common sexually transmitted infections, and partners of HCV and HIV co-infected persons are at the highest risk of acquiring HCV sexually.

In many cases of HCV infection, no recognizable transmission factor or route is identified (Memon and Memon 2002).

Clinical manifestations

The incubation period for hepatitis C before the onset of clinical symptoms ranges from 6 to 7 weeks on average. In acute infections, the most common symptoms are fatigue and jaundice; however, the majority of cases (between 60 and 70 per cent), even those who develop chronic infection, are asymptomatic for years. Fulminant hepatitis C forms are very rarely observed. While most patients with acute HCV infection have mild symptoms or no symptoms, 50–85 per cent of those infected develop chronic disease. Chronic disease is difficult to recognize because symptoms are mild and infection passes silently and insidiously from the acute to the chronic phase. Serological diagnosis of acute HCV infection is mainly based on recent HCV antibodies (anti-HCV) seroconversion. Persistence of HCV infection is diagnosed by the presence of HCV RNA in the blood for at least 6 months. The mechanisms of HCV persistence are currently unknown, although it is known that HCV chronicity develops despite humoral and cellular responses to HCV proteins. Factors associated with development of chronic disease appear to include older age at the time of infection, male gender, and an immunosuppressed state such as HIV infection (Lauer and Walker 2001).

Extra-hepatic manifestations of hepatitis C

Hepatitis C virus infection provokes dysfunction in B-lymphocytes with extra-hepatic manifestations of autoimmunity.

Many autoimmune and metabolic diseases have been associated with HCV infection: lichuen planus, granuloma annulare, porphyria cutanea tarda, and psoriasis (Andrade et al. 2012). The most important expression of autoimmunity in HCV carriers is HCV-related cryoglobulinaemia, which can cause purpura, vasculitis, glomerulonephritis, and peripheral neuropathy (Atta et al. 2010). A higher level of cryoglobulinaemia has been found in HCV carriers with lymph proliferative disorders, mainly B-cell non-Hodgkin lymphoma (Yu and Lin 2013).

Furthermore, HCV infection has been associated with higher risk of insulin resistance and diabetes (Naing et al. 2013). On the other side diabetes is a confirmed risk factor for the evolution to hepatocellular carcinoma.

The presence of non-organ specific autoantibodies is another expression of autoimmunity found in HCV carriers, which has been associated in some studies with advanced fibrosis and failure in the treatment of hepatitis C with the combined therapy of interferon- α plus ribavirin. Antibodies to self-antigens such as nucleoproteins (ANA), smooth muscle (SMA), liver-kidney microsomal type-1 antigen (LKM-1), immunoglobulin G (RF), neutrophil cytoplasm (ANCA), and phospholipids (APL), which are routinely used as biomarkers of autoimmune diseases, can be found in HCV-carriers with varying prevalence. Their induction seems mainly to involve immune cross-reactions caused by molecular mimicry between HCV polypeptide and human auto antigens (Atta et al. 2010).

Treatment

The primary goals for treatment of HCV infection are to reduce morbidity and mortality through complete clearance of HCV and normalization of liver enzymes, reducing disease progression, improving quality of life, and reducing the reservoir of chronic carriers, thereby controlling further transmission. In contrast with hepatitis B, chronic HCV infection is potentially curable. Virological cure or sustained viral response is defined by the persistence of negativity of HCV-RNA 6 months after ending therapy.

Treatment is recommended for patients with an increased risk of developing cirrhosis or with potential harmful extra-hepatic manifestations of HCV; most of these patients (but not all) have persistently elevated liver enzymes.

In patients with cirrhosis, the benefits of therapy will be: reduction of the risk of decompensation, reduction of the risk of evolution to hepatocellular carcinoma, and reduction of the risk of dying from a liver-related death (Veldt et al. 2007).

Effective sustained viral response has been obtained in about 50 per cent of HCV patients with genotype 1 and 80 per cent of patients with genotypes 2 or 3 who had received combined weekly pegylated interferon-based treatment with daily ribavirin for 48 weeks (Chevalier and Pawlotsky 2007; Tan and Lok 2007). This negativity of HCV-RNA 6 months after the end of therapy is maintained in 99 per cent of all patients.

More recently, the introduction of new drugs (boceprevir and telaprevir) in the HCV therapeutic schedule, increased the chance of sustained viral response (SVR) to 70 per cent in naive patients and to almost 80 per cent in patients who relapsed after the standard treatment with peginterferon + ribavirin. However, the triple therapy seems to have more adverse events, namely anaemia in boceprevir and anaemia and cutaneous rash in telaprevir (Jacobson et al. 2011; Kwo et al. 2010).

The therapy for chronic HCV is too costly for most patients in low- and middle-income countries to afford. The new drugs make the treatment cost higher, even for industrialized countries. Besides, the adverse events during treatment require multidisciplinary medical care and personnel with solid expertise to manage this treatment. Unfortunately, they are not available in most countries.

There are new oral and more specific drugs arriving, without the need for interferon or even ribavirin. They inhibit several regions of HCV (e.g. polymerase) having an efficacy estimated to be around 80–90 per cent in 12 weeks of therapy (Suzuki et al. 2012).

Public health impact

HCV has been compared to a 'viral time bomb'. The WHO estimates that about 150 million people, that is, some 2 per cent of the world's population, are infected with HCV; 75–80 per cent of them are chronic HCV carriers at risk of developing liver cirrhosis and/or HCC. It is estimated that 3–4 million persons are newly infected each year and that 20 per cent of those infected with HCV progress to cirrhosis within the first 10 years after infection (Alter 2007; Gerberding and Henderson 1992). Although the prevalence of chronic HVC reached a peak in 2001 (according to a multiple cohort model) in the United States, the prevalence of hepatitis C cirrhosis and its complications will continue to increase through the next decade (Davis et al. 2010). In Europe the prevalence of chronic hepatitis C in the last decade was 0.13–3.26 per cent. It

is of great concern that about 90 per cent of people in Europe infected by viral hepatitis are unaware of their status (Blachier et al. 2013). Furthermore, chronic HCV disease is the primary indication for liver transplantation in industrialized countries (Adam et al. 2012).

Prevention

There is no vaccine against HCV. Research is in progress, but the high mutability of the HCV genome complicates vaccine development. Although 20–35 per cent of patients with acute HCV infection clear the virus spontaneously, lack of knowledge of any protective immune response following HCV infection impedes vaccine research. Although some studies have shown the presence of virus-neutralizing antibodies, it is not fully clear whether and how the immune system is able to eliminate the virus. Thus, from a global perspective, the greatest impact on HCV disease burden will likely be achieved by focusing efforts on reducing the risk of HCV transmission from nosocomial exposures (e.g. screening of blood, rigorous implementation of infection control, reducing unsafe injection practices) and high-risk behaviours (e.g. injection drug use).

Adherence to fundamental infection control principles, including safe injection practices and appropriate aseptic techniques, is essential to prevent transmission of blood-borne viruses in healthcare settings. Educational programmes aimed at the prevention of drug use and, for those already addicted, aimed at the prevention of shared needles and other equipment can decrease this source of infection. Some countries have established needle exchange programmes that provide easy access to sterile needles and syringes, accompanied by counselling and health education and instructions on the safe disposal of used syringes.

Alcoholic liver disease

Alcoholic beverages have been used in human societies since the beginning of recorded history. In 2005, a study estimated that just over 40 per cent of the world's adult population consumes alcohol

and the average consumption per drinker is 17.1 L per year (Shield et al. 2013).

It has long been known that alcohol consumption is responsible for increased illness and death. Worldwide, alcohol causes 2.5 million deaths each year, including 320,000 young people between the age of 15 and 29 (9 per cent of deaths in that age group) and 693 million (4.5 per cent of total) disability-adjusted life years (DALYs) (WHO 2011a, WHO 2011b). The burden is not equally distributed among countries. The highest disease load attributable to alcohol is found in the heavy-drinking former socialist countries of Eastern Europe and in Latin America (Fig. 8.16.3). For most diseases there is a dose–response relation to the volume of alcohol consumption, with the risk of the disease increasing with higher volume.

Alcoholic liver disease, resulting from the chronic and excessive consumption of alcoholic beverages, represents a considerable burden for the practising clinician, constituting the commonest reason for admitting patients with liver disease to a hospital. Alcohol (37 per cent), viral hepatitis (39 per cent), or both (4 per cent) are the leading indications for liver transplantation following cirrhosis, representing 57 per cent of transplants in Europe (European Liver Transplant Registry 2011) (Fig. 8.16.4), and alcohol is responsible for 50 per cent of deaths due to liver cirrhosis (WHO 2011c).

The costs to society from alcohol abuse cannot be overemphasized. In 2006, overall costs in the United States reached US\$223.5 billion, out of which healthcare expenses accounted for 11 per cent. Almost three-quarters of these costs were due to binge drinking (Bouchery et al. 2011). Despite this burden, surprisingly little consensus exists on disease pathogenesis and on the factors that determine susceptibility.

Worldwide patterns of alcoholic intake and burden of disease in general and alcoholic liver disease in particular

Patterns of alcohol intake are constantly evolving as well as the prevalence and incidence of alcoholic liver disease. In 2010, 5.5

per cent of the global burden of disease was attributable to alcohol. This is almost as much as the burden of disease from tobacco (6.3 per cent) (Lim et al. 2012). Alcohol use represented the leading risk factor for global disease burden in Eastern Europe, most of Latin America, and southern sub-Saharan Africa. Given the relationship between alcohol consumption and cirrhosis (Sheron et al. 2008), it would be expected that there is a lag period between changes in per capita alcohol consumption and cirrhosis-related mortality. Data regarding this lag effect have been conflicting. In fact, a long latency time is not observed, and the usual lag period is only one year or less (Kerr et al. 2000).

Morphology and natural history of alcoholic liver disease

Fatty liver (steatosis)

The first and most predictable hepatic change attributable to alcohol is the development of large droplet (macrovesicular) steatosis. This disorder usually resolves within 2 weeks if alcohol consumption is discontinued (Diehl 1997). In the past, it was assumed that alcoholic fatty liver was a benign process. However, it is now assumed that 5–15 per cent of patients will develop cirrhosis during a 10-year follow-up period (Sorensen et al. 1984).

Alcoholic steatohepatitis

The spectrum of alcoholic steatohepatitis includes fatty infiltration of hepatocytes associated with hepatocellular injury including ballooning degeneration, Mallory bodies inflammation with neutrophils and/or lymphocytes, and fibrosis with a perivenular, perisinusoidal, and pericellular disposition. These changes are present in 10–35 per cent of all alcoholics. It is not a benign process. Some patients will develop fatal decompensation. In addition, the risk of developing cirrhosis is increased. It is estimated that the probability of developing cirrhosis is 10–20 per cent per year and 70 per cent of patients with alcoholic hepatitis will eventually develop cirrhosis (Diehl 1997).

Cirrhosis

The main causes for cirrhosis are: HBV (worldwide), HCV (in Europe), and alcohol (Cortez-Pinto et al. 2010). In 2010, more than

1 million deaths (2 per cent of all deaths) were due to liver cirrhosis. Alcoholic cirrhosis accounts for 48 per cent of cirrhosis-related deaths (Rehm et al. 2013). The long-term prognosis of alcoholic cirrhosis improves with abstinence. The 5-year survival in compensated cirrhosis patients who continue to drink is 70 per cent, but can be as high as 90 per cent if they abstain from further alcohol intake. In patients with decompensated cirrhosis, the 5-year survival drops to 30 per cent in individuals who continue to drink, but is 60 per cent in those who stay abstinent (Alexander et al. 1971; Diehl 1997).

Hepatocellular carcinoma

Alcohol can be considered both as a primary cause of HCC and as a co-factor for the development of HCC. Most of the studies on incidence of HCC in alcoholic cirrhosis date from before the identification of the HCV. As hepatitis C is relatively frequent in alcoholics, the proportional contribution of alcohol in the reported HCC incidence rates in earlier studies is likely to be overestimated. Although the exact annual incidence rate of HCC in alcoholic cirrhosis is unknown, it is estimated to be over 1.5 per cent, making it worthwhile to offer patients testing (Bruix and Sherman 2005).

Factors influencing the risk of alcoholic liver disease

Most authors agree that persons who drink heavily (50–60 g of ethanol daily) represent a population at increased risk of developing liver disease (Becker et al. 2002). However, the absolute risk of acquiring alcoholic hepatitis or cirrhosis is relatively low (6.9 per cent in the mentioned study). This suggests that genetic factors and/or environment play a role in disease risk. Many studies that address the risk factors refer to their effect on 'alcoholic liver disease' in general rather than any specific aspect of alcoholic liver disease such as steatohepatitis.

Amount of alcohol

There is a general agreement that excessive alcohol consumption is associated with an increased risk of cirrhosis. However, the exact dose or a specific dose–response relationship for cirrhosis has not been agreed on. Evidence suggests that there is an increased risk for alcoholic liver disease with the ingestion of 60–80 g/day of alcohol in men and 20 g/day in women (Day 2000). 'Safe' limits of alcohol consumption for the liver are up to one–two drinks per day for women, and up to three–four drinks per day for men, with at least three alcohol-free days per week (European Association for the Study of the Liver 2012; Michielsen and Sprengers 2003).

Drinking behaviour

Researchers from Denmark showed in a large survey of 30,630 persons that beer or spirits are more likely to promote liver disease than wine (Becker et al. 2002). At present, it is uncertain whether wine per se is responsible for this reduced risk of liver disease compared to the other alcoholic beverages, or whether it represents a surrogate for other healthy behaviours such as increased consumption of fruits/vegetables (Everhart 2003).

Binge-drinking, a mode of social behaviour nowadays, is the exaggerated form of non-mealtime drinking. It has been reported to increase the risk of alcoholic hepatitis fivefold (Barrio et al. 2005), and to increase the risk of all-cause mortality in men and women (Tolstrup et al. 2004). Also drinking multiple types of

alcohol has been shown to be related to the risk of cirrhosis and non-cirrhotic liver disease (Naveau et al. 1997).

Gender

It is well recognized that women are more susceptible to alcohol-induced health disorders than men. Men and women have similar sized livers and when the rate of alcohol metabolism is normalized to liver mass, men and women have similar metabolic rates. However, blood alcohol levels after comparable doses of alcohol will usually be higher in women than in men because of their lower body volume and the higher percentage of their body mass consisting of fat. Evidence from animal models has suggested that oestrogen increases the gut permeability to endotoxin and accordingly upregulates endotoxin receptors of Kupffer cells leading to an increased production of tumour necrosis factor alpha in response to endotoxin (Enomoto et al. 1999). It is also known that the gastric alcohol dehydrogenase activity can be different in men and women (Parlesak et al. 2002).

Co-morbid conditions

Individuals with co-morbid conditions affecting the liver exhibit a greater tendency to develop liver disease in response to alcohol consumption than persons being otherwise healthy (Fattovich et al. 2004). This was clearly demonstrated in the case of hepatitis C (Corrao and Arico 1998), hepatitis B, hereditary haemochromatosis (Fletcher et al. 2002), and obesity (Naveau et al. 1997) and most probably applies to other causes of chronic hepatitis.

Genetic polymorphisms

Epidemiological evidence is strong for the existence of heritable susceptibility to alcoholic liver disease. This appears related to several gene polymorphisms, some of which impact alcohol metabolism and others that influence hepatic immune responses.

Non-alcoholic fatty liver disease and non-alcoholic steatohepatitis

Definitions

Steatosis is defined as the accumulation of fat in the liver parenchymal cells or hepatocytes. A distinction is made between macrovesicular and microvesicular steatosis. Macrovesicular steatosis implies the presence of large fat vacuoles, containing predominantly triglycerides, and occupying a large part of the cell cytoplasm, displacing the nucleus towards the cell border. The hepatocytes may be enlarged by the presence of these fat vacuoles. Macrovesicular steatosis is graded according to the percentage of hepatocytes containing fat vacuoles: less than 5 per cent is minimal or no steatosis; 5 to 30 per cent is mild steatosis; over 30 to 60 per cent is moderate; and greater than 60 per cent is considered to be severe macrovesicular steatosis (D'Allessandro et al. 1991). In microvesicular steatosis, bipolar lipids are forming micelles, which are spread over the cytoplasm, and which do not displace the nucleus. The cells usually have normal dimensions. Grading is less complex: 45 per cent is considered to be severe microvesicular steatosis (Sheiner et al. 1995). In many patients, both types of steatosis are present, called mixed type steatosis. In those cases, macrovesicular steatosis is usually predominant.

Two terms have been used interchangeably in the past two decades to describe fat accumulation in hepatocytes. These include *non-alcoholic fatty liver* (NAFL) and *non-alcoholic fatty liver*

disease (NAFLD). While NAFL has been linked to constitutional fatty infiltration of hepatocytes, which is not necessarily associated with an inflammatory response or fibrosis, NAFLD has been linked to an active hepatic injury pattern, inflammation and fibrosis. However, there is no consensus regarding the use of these two terms and the distinction between them. Regardless, in NAFL or NAFLD, steatosis is present, and alcohol is excluded as a cause of the steatosis (Harrison et al. 2004). The maximum daily alcohol consumption allowed for the definition of NAFLD is 10 g (Byrne and Wild 2010). The diagnosis of alcohol consumption relies on thorough anamnesis and hetero-anamnesis, with a detailed 7-day diary of alcohol use. Laboratory parameters are non-specific and even carboxy-deficient transferrin measurement is not very accurate in excluding significant alcohol consumption. In addition, the differential diagnosis cannot be made histologically, as the histological features of alcoholic and non-alcoholic liver disease seem to be identical. The diagnosis of the aspect of 'non-alcoholic' therefore constitutes a first problem in the interpretation of any data on the prevalence and natural history of NAFLD.

Non-alcoholic steatohepatitis (NASH) is a subgroup of NAFLD, in which liver steatosis is accompanied by signs of liver cell damage (especially ballooning of hepatocytes) and/or inflammation. In these patients, fibrous tissue may be generated, and patients can evolve to cirrhosis and its complications, including HCC. Although still debated, it is generally believed that pure steatosis does not lead to fibrogenesis, but steatosis is a *sine qua non* condition to NASH. NASH patients are more likely to have progressive liver disease (Angulo 2002).

Although not reflected by the name, NAFLD also implies the exclusion of other chronic liver diseases, including chronic viral hepatitis, toxic hepatitis (due to industrial toxins or solvents or to pharmacological agents), autoimmune liver disease, haemochromatosis, Wilson's disease, and some rare metabolic disorders. Hepatitis C, especially genotype 3, and Wilson's disease are two classical examples of liver diseases accompanied by steatosis, but they are not NAFLD. As will be discussed further, steatosis is no longer regarded as an innocent bystander, therefore the term NAFLD is preferred over NAFL.

Diagnosis

A first problem is the diagnosis of the aspect 'non-alcoholic'. Patients may not accurately report the quantity of alcohol they consume. Laboratory tests, including elevation of AST (aspartate transaminase) more than ALT (alanine transaminase), elevation of γ -GT (gamma-glutamyl transpeptidase) or CDT (carboxy-deficient transferrin) measurement may be helpful, but are inaccurate. Thorough anamnesis and hetero-anamnesis is the cornerstone of the diagnosis, which therefore may always remain questionable.

A second problem is the diagnosis of steatosis and steatohepatitis. Abdominal ultrasound has a sensitivity of 70–75 per cent and a specificity of 60–70 per cent in diagnosing moderate to severe steatosis (Bellentani et al. 2000). Computed tomography scanning and magnetic resonance imaging are equally specific (100 per cent) and sensitive (75 per cent) in making the same distinction (Rinella et al. 2001). These non-invasive tools are thus not very sensitive, not able to accurately grade the steatosis, and not able to diagnose the presence of inflammation or fibrosis, and hence do not distinguish between NAFLD and NASH. Magnetic resonance spectroscopy can accurately quantify the fat content of a

liver sample, but the need for specific software and practical considerations limits its use to specific research centres. Scores based on laboratory parameters are not validated for the diagnosis of steatosis (Miele et al. 2007). The gold standard for the diagnosis still is liver biopsy. The invasive character of that procedure, however, limits its use on a larger scale.

The diagnosis of steatohepatitis is even more complicated. Laboratory tests, especially the elevation of aminotransferase levels, are inaccurate, although frequently regarded as a sign of liver cell damage and hence inflammation. Patients with elevated liver tests may have pure steatosis without inflammation on liver biopsy, and 50 per cent of the patients with biopsy-proven steatohepatitis have normal transaminases (Prati et al. 2002). The cut-off values for normal aminotransferase levels have recently been questioned, and lowering the upper limit of normal to 30 U/L in males and 19 U/L in females increases the sensitivity for the diagnosis of NASH from 42 per cent to 80 per cent, but specificity decreases from 80 per cent to 42 per cent (Kunde et al. 2005). Scoring systems based on laboratory parameters have been studied and need further validation. Imaging cannot distinguish steatosis from steatohepatitis. Again, liver biopsy is the gold standard. This also holds true for the diagnosis of fibrosis. Laboratory parameters are not useful, except for a stage of cirrhosis, where more specific laboratory features can be present. Imaging is not useful for the staging of fibrosis, and is only of value if signs of cirrhosis indicate advanced liver disease. Elastography, an ultrasound-based technique measuring liver stiffness (Ganne-Carrie et al. 2006), has been validated in hepatitis C, but not in NASH, and, like laboratory scoring systems, only roughly distinguishes between no or mild versus severe fibrosis and cirrhosis. Also for fibrosis, liver histology is still the gold, or at least the best, standard (Miele et al. 2007). More data are needed to approve elastography (Fibroscan®) or other non-invasive methods for clinical assessment of NASH (Friedrich-Rust et al. 2010).

Prevalence of steatosis, NAFLD, and NASH

As already mentioned, the difficulty in diagnosing non-alcoholic steatosis, and the lack of accuracy of the tools for the diagnosis of steatosis, constitute two major problems in the acquisition of precise epidemiological data. Sample selection constitutes a third problem, as some categories of patients are more at risk. In screening studies with ultrasound, prevalence varies between 16 and 23 per cent (Bellentani et al. 2000). In an autopsy series of traffic accidents, steatosis was histologically diagnosed in 24 per cent of cases. The prevalence was clearly age related: in those aged 20 years, the prevalence was 1 per cent, while in those aged 60 years the prevalence rose to 39 per cent (Hilden et al. 1997). Based on these figures, and making the distinction with alcoholic steatosis, the prevalence of non-alcoholic steatosis is estimated at 15–20 per cent in the general adult population (Angulo 2002). Exact data on the prevalence of NASH in the general population are scarce. In an autopsy series, a prevalence of 6.3 per cent was reported. The prevalence is usually estimated at 2 per cent, but this highly depends on sample selection. As a number of risk factors can be identified (see following subsections), prevalence rates may vary geographically (Neuschwander-Tetri and Caldwell 2003).

NAFLD and NASH and the metabolic syndrome

The metabolic syndrome, associating visceral overweight, dyslipidaemia, hyperinsulinaemia or diabetes mellitus, and arterial

Table 8.16.2 Diagnosis of metabolic syndrome according to ATP III

Risk factors	Limits
Central obesity (waist circumference):	
Male	> 102 cm
Female	> 88 cm
Triglycerides	≥ 150 mg/dL
High-density lipoprotein cholesterol:	
Male	< 40 mg/dL
Female	< 50 mg/dL
Arterial blood pressure	≥ 130/ ≥ 85 mmHg
Fasting glycaemia	≥ 100 mg/dL

hypertension, as defined by the Third Report of the National Cholesterol Education Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel-ATP III) (Expert Panel 2001), seems to be closely related with NAFLD and NASH. Some authors consider NAFLD and NASH as the hepatic manifestation of the metabolic syndrome. Many epidemiological data support a close relationship between the two entities.

In patients with NAFLD, the metabolic syndrome, according to the criteria of the ATP III (Table 8.16.2), is fully present in 30 per cent of males and 60 per cent of females. Visceral adiposity is present in 40 per cent and 65 per cent of males and females, respectively, and diabetes in 10 per cent and 30 per cent, respectively. These prevalence rates are significantly higher than in the control population. The metabolic syndrome is significantly more prevalent in patients with NASH compared to patients with simple steatosis (38 per cent vs 14 per cent, $p = 0.004$) (Marchesini et al. 2003).

In patients with obesity, steatosis is present in 60–95 per cent, according to the selection of patients and the procedure used for diagnosis (e.g. ultrasound or histology in a series of patients undergoing bariatric surgery). The body mass index (BMI) is an independent predictive factor for the accumulation of fat in the liver (Marchesini et al. 2003).

Globally, the prevalence of overweight and obesity has increased since 1980, and the increase has accelerated. The global age-standardized prevalence of obesity nearly doubled from 6.4 per cent in 1980 to 12.0 per cent in 2008. Half of this rise occurred in the 8 years between 2000 and 2008 (Stevens et al. 2012). This increase of the prevalence of overweight in children and adolescents is of particular concern. The prevalence of diabetes is also increasing, and was estimated at around 9 per cent worldwide in 2008 (Danaei et al. 2011). In the United States, 22 per cent of the adult population fulfils the criteria of the metabolic syndrome (Lin and Pi-Sunyer 2007).

The natural history of NAFLD/NASH

Data on the natural history of NAFLD and NASH have the same three problems as outlined for the prevalence data. In patients with NASH, 45 per cent will exhibit fibrosis progression and 19 per cent will ultimately develop cirrhosis (Fassio et al. 2004). In patients with NAFLD, lifetime progression to cirrhosis is estimated at 2–5 per cent (Dam-Larsen et al. 2004; Ekstedt et al. 2006).

It is not clear whether only NASH patients will progress, or if pure steatosis may also lead to progressive fibrosis and ultimately cirrhosis. A long-term follow-up study (mean follow-up of 13.7 years) showed no increase in mortality in patients with elevated liver enzymes and pure steatosis on an initial biopsy. Patients with biopsy-proven NASH, on the other hand, had a higher risk of dying from cardiovascular disease (15.5 per cent vs 7.5 per cent, $p = 0.04$) and from liver-related causes (2.8 per cent vs 0.2 per cent, $p = 0.04$). Disease progression was, however, noted: 41 per cent had fibrosis progression and 5.4 per cent of patients developed cirrhosis, and this did not depend on features of inflammation on the initial biopsy (Ekstedt et al. 2006).

In patients with cryptogenic cirrhosis, more than 60 per cent have features that might have been associated with NASH and in these patients cirrhosis is believed to be an end stage of NASH (Ekstedt et al. 2006). Actually cryptogenic cirrhosis accounts for 8 per cent of the indications for liver transplantation in Europe (European Liver Transplant Registry 2011). NASH may recur after liver transplantation, further enforcing the concept of NASH as aetiology of cryptogenic cirrhosis (Maheshwari and Thuluvath 2006).

HCC has been reported in patients with NASH-associated cirrhosis. Data on prevalence and risk, however, are scarce. In the Ekstedt series (Ekstedt et al. 2006), 2.3 per cent developed HCC or 43 per cent of those with documented cirrhosis. It is thus not clear whether the risk is comparable to the 10 per cent cumulative risk usually reported in cirrhosis of any aetiology, but it might be higher (Smedile and Bugianesi 2005). HCC has not been reported without cirrhosis or extensive fibrosis. With the obesity epidemic, it is expected that HCC related to NASH will become more frequent (White et al. 2012).

Risk factors reported to be associated with an increased risk of fibrosis are: age (40 or 50 years of age), the presence of diabetes, BMI 25 or 28 or 30, hypertriglyceridaemia, elevated transaminases two times the upper limit of normal, and AST/ALT 1 (Angulo et al. 1999; Adams et al. 2005). Patients with NAFLD and diabetes have a higher probability of cirrhosis and liver-related death, compared to NAFLD patients without diabetes (Abrams et al. 2004). In the Ekstedt series (Ekstedt et al. 2006), the 41 per cent progression of fibrosis was associated with higher levels of ALT, a higher weight gain during follow-up, more severe insulin resistance and more pronounced fatty infiltration. As stated previously, patients with NASH more frequently meet the criteria of the metabolic syndrome and are more likely to have visceral obesity compared to patients with simple steatosis. As it is believed that NASH is a subgroup of NAFLD at risk for progressive fibrosis, the metabolic syndrome and its components clearly constitute a risk factor for fibrosis and cirrhosis, which will be a major burden of disease in view of the epidemic of obesity and diabetes and their related conditions.

Treatment

No specific treatment is clearly defined for NASH, but there is a consensus concerning implementation of behavioural measures as well as treating cases of advanced disease (Chuthan Sourianarayanan et al. 2013). NASH treatment is driven by the stage of the disease. In more advanced stages, drugs must be added to classical behavioural measures. Up to now, it is clear that patients with NASH benefit from physical exercise and balanced,

well oriented diets, probably through weight loss and decreased insulin-resistance (Carulli et al. 2013).

Pharmacological treatment adjuvants for weight losing may be considered in some selected cases. Orlistat and sibutramine have been used, but their indication is limited due to their adverse side effects.

Bariatric surgery is recommended in patients with a BMI greater than 40 kg/m² or BMI greater than 35 kg/m² and co-morbidities. This procedure is highly effective and may be indicated even in patients with well compensated cirrhosis, but it has high risk of morbidity if the patients have portal hypertension.

For patients who evolved toward advanced liver disease or HCC, liver transplantation can be indicated, although NASH relapse post transplantation is quite frequent.

Specific pharmacotherapy includes drugs used to treat metabolic syndrome, as well as drugs with putative antioxidants effects. The most prescribed drugs are insulin-sensitizers (metformin and pioglitazone). A recent meta-analysis compared the results of the studies that involved these drugs and concluded that pioglitazone is superior compared with metformin (Musso et al. 2010), but pioglitazone has been associated with potential harmful adverse events, such as heart failure and bladder cancer.

Antioxidants are considered promising drugs for NASH, but the studies are considered preliminary. Among the putative antioxidant drugs, vitamin E has been evaluated as having the most consistent results, even with documented amelioration in liver pathology (Sanyal et al. 2010). On the other hand, prolonged use of vitamin E has been associated with adverse reactions such as risk of cerebral vascular haemorrhage, coagulation disturbance and prostatic disorders.

Despite benefits observed in the above mentioned drug therapies, the long-term use of these drugs on NASH in terms of efficacy and safety remains unknown.

Overall conclusion

In spite of the availability of safe and effective vaccines and their proven effectiveness in reducing the chronic consequences of HBV infections, the current burden of disease associated with hepatitis B remains substantial. To finally achieve the WHO goal of HBV elimination, continuous efforts will be required to keep prevention of hepatitis B on the agenda of public health officers worldwide, and to continue to improve treatment options for those already suffering chronic hepatitis B.

Even if the present burden of disease caused by hepatitis C is somewhat less impressive, the lack of an effective vaccine despite major efforts in its development, and the increased burden of chronic liver disease resulting from the high rates of HCV infection 20–30 years ago (the baby boomer generation, born 1946–1964), pose a substantial future threat to public health.

Alcoholic liver disease remains a major cause of morbidity and mortality worldwide. There is concern that, worldwide, alcoholic liver disease may increase in the next several decades. Recent data indicate that alcohol consumption is increasing in low- and middle-income countries. In addition, rates of excessive alcohol intake appear to be rising in women and binge drinking has become a common pattern of excessive alcohol use. Although alcohol-related cirrhosis mortality rates decreased in many countries during the past 30 years, rates are no longer

declining in several countries and are actually increasing in low- and middle-income countries.

Although data on the prevalence and natural history of NAFLD/NASH are scarce and suffer from multiple methodological problems, it is clear that, because of their association with the metabolic syndrome and its components, which are increasing to epidemic proportions in the Western population, NAFLD and NASH will constitute a major health problem in the near future.

Key points

- ◆ Liver cirrhosis and primary liver cancer are important public health problems worldwide, killing more than 1 million people each year. Liver cancer is the third most common cause of deaths from cancer.
- ◆ Viral hepatitis B and C, and alcoholic as well as non-alcoholic fatty liver disease, represent the major causes for chronic liver diseases. All have oncogenic potential.
- ◆ Despite the availability and widespread use of effective hepatitis B vaccines, efforts will be required to keep the immunization programmes on the political and donor agenda.
- ◆ As the development of a hepatitis C vaccine has not yet resulted in success, prevention and control measures will form a major challenge to all those involved in public health. Easy and equal access to the new antiviral treatments is of the utmost importance.
- ◆ In low- and middle-income countries experts predict a future wave of alcohol-related liver diseases.
- ◆ Fatty liver disease and steatohepatitis and chronic liver diseases associated with the metabolic syndrome, may rise to epidemic proportions in the near future in Western populations.

Emerging and re-emerging infections

David L. Heymann and Vernon J. M. Lee

Introduction to emerging and re-emerging infections

The microbial world is complex, dynamic, and constantly evolving. Infectious organisms reproduce rapidly, mutate frequently, cross the species barrier between animal hosts and humans, and adapt with relative ease to their new environments. Because of these characteristics, infectious organisms are able to alter their epidemiology, their virulence, and their susceptibility to anti-infective drugs.

When disease is caused by an organism that is newly identified and not known previously to infect humans or has changed in susceptibility to an anti-infectious drug, it is commonly called an emerging infectious disease, or simply an emerging infection. When disease is caused by an infectious organism previously known to infect humans that has re-entered human populations or changed in epidemiology, it is called a re-emerging infection. A report published by the United States Institute of Medicine in 1992 first called attention to emerging and re-emerging infectious diseases as evidence that the fight against infectious diseases was far from won, despite great advances in the development of anti-infective drugs and vaccines (Lederberg et al. 1992).

All forms of infectious organisms—bacteria, viruses, parasites, and prions—are able to emerge or re-emerge in human populations, and it is estimated that up to 70 per cent or more of all emerging infections have a source in animals (zoonotic infections). When a new infectious organism enters human populations there are several potential outcomes. Infected humans may become ill or remain asymptomatic. Once humans are infected, human-to-human transmission may or may not occur. If it occurs, it may be limited to one, two, or more generations, or it may be sustained indefinitely. Among those infectious organisms that cause disease, some maintain their virulence, while others appear to attenuate over time. Changes in the epidemiological characteristics of infectious organisms may occur gradually through a process of adaptation, or they may occur abruptly as the result of a sudden genetic exchange during reproduction and/or replication.

Epidemiology of emerging and re-emerging infections

Many factors influence the transmission of an infectious organism to and among humans including the type of organism, the

incubation period (time from exposure to the infectious organism to clinical disease and infectiousness), clinical outcomes, mutations, and human genetics.

Infections of limited human-to-human transmission

Rabies is a zoonotic infection that commonly occurs after the bite of a rabid animal, and variant Creutzfeldt–Jakob disease (vCJD) is a zoonotic infection associated with beef and bovine spongiform encephalopathy (BSE) or ‘mad cow disease’. These infections cause illness in humans but cannot transmit from one human to another unless there is iatrogenic transmission through non-sterile medical procedures, blood transfusion, or organ transplant. In several instances, corneal transplantation from a person who died with undiagnosed rabies infection has caused rabies in transplant recipients. The recent identification of several humans with vCJD associated with blood transfusion demonstrates its potential to spread iatrogenically within the human population.

Other zoonotic infections in humans are able to initially transmit from person to person, but then are unable to sustain transmissibility. Thought to have a rodent reservoir in the sub-Saharan rain forest, the monkeypox virus infects humans who come in contact with an infected animal. Transmission is sustained through one or two generations and then ceases. In the first generation of cases, the case fatality rate can approach 10 per cent, but with passage through human populations the virulence and case fatality of human monkeypox appear to decrease as its transmissibility declines. The monkeypox virus caused a limited, multistate outbreak in the United States in 2003, linked to Gambian giant rats imported from West Africa and distributed to pet shops as exotic pets. In the pet shops, prairie dogs, thought to have been the source of the outbreak, appear to have been infected with the monkeypox virus by the Gambian giant rats, and they then transmitted the virus onwards to humans (Guarner et al. 2004).

Another zoonotic infectious organism with limited human-to-human transmission is the Ebola virus. With a relatively short incubation period, infection leads to rapid progression to disease with a severe and often fatal outcome that limits the potential for contact of infected humans with others. The potential for attenuation of the Ebola virus with passage is unknown, though in its present form it is generally agreed that it is unlikely that it will

be able to sustain transmission. The Ebola outbreak in 2014 in West Africa spread more widely than previous outbreaks due to the lack of a robust response when it was first identified. The same time-proven response measures can stop outbreaks: hospital infection control and protection of health workers, contact tracing with contacts placed under surveillance and isolation if Ebola symptoms develop, and community health education on transmission, burial practices, and prevention. The 2014 outbreak spread in an area where health systems were being rebuilt after years of civil strife and there was thus inadequate infection control, low access to healthcare, and great movement of populations. This led to the WHO declaration of a Public Health Emergency of International Concern and control remains possible with adequate resources.

Infections with sustained transmission

Infection with the human immunodeficiency virus (HIV), thought to have emerged from a non-human primate sometime in the late nineteenth or early twentieth century, has a long incubation (latent) period during which it is difficult to detect clinically. Though amplification of transmission is thought to have begun during the 1970s through risky sexual behaviour, HIV escaped detection until the early 1980s by which time it had already spread throughout the world and caused a series of epidemics that led to its endemicity. During 2010, HIV was estimated to have caused 2.7 million human infections and 1.8 million deaths worldwide, placing it high on the list of causes of human morbidity and mortality (UNAIDS 2011).

One common infectious organism that is able to sustain transmission—the influenza virus—demonstrates the great diversity of infectious organisms. The RNA viruses that cause seasonal human epidemics of influenza are highly unstable genetically and mutate frequently during replication. Mutation, or genetic drift, results in susceptibility of individuals regardless of their exposure to the viruses before drift, requiring annual antigenic modifications in seasonal influenza vaccines to ensure protection. The short incubation period, and the mild illness caused by the majority of infections, especially among school aged children, result in rapid transmission potential that leads to seasonal influenza epidemics.

At the same time, different subtypes of influenza viruses are found across a variety of avian species, and these occasionally infect humans directly from birds, or from intermediary animal populations that have been infected by birds. The H5N1 avian influenza virus that was first identified in Hong Kong as the cause of human illness in 1997 continues to cause occasional severe infections in humans but remains a zoonotic human infection and does not transmit easily from person to person. This virus, however, like many other avian influenza viruses has the potential to mutate and gain the epidemiological characteristics that would permit it to spread easily among humans to cause an epidemic or a pandemic. Pandemics are, by definition, infectious disease outbreaks that spread across the world, and they are the result of the lack of immunity to a new infectious organism to which there has been no previous human exposure. The highly fatal 1918 influenza pandemic is thought to have originated from an avian influenza virus that may have undergone adaptive mutation in non-human mammals over time, attaining human transmissibility characteristics before

crossing the animal/human species (Taubenberger and Morens 2006).

Other influenza pandemics in 1957, 1968, and 2009 are thought to have been caused by genetic reassortments during the intracellular replication process in an animal dually infected with viruses containing human and avian influenza genetic components (Guan et al. 2010; York and Donis 2013). The 2009 H1N1 pandemic influenza virus showed genes from swine, avian, and human influenza. Though the 2009 pandemic virus is thought to have its origins in the Americas, risk factors for emergence of influenza viruses in humans are thought to be highest in areas such as South China and South East Asia where there are large populations of aquatic birds (the hosts of many different types of avian influenza viruses) and where humans live in close proximity to animals such as pigs that may be easily infected by these aquatic birds.

Geographic distribution of emerging and re-emerging infections

Emerging infections have the potential to occur in every country and on every continent (Fig. 8.17.1). Though the term emerging infections was introduced in the early 1990s, the previous 40 years had seen a panoply of newly identified infections in humans on every continent. The year 1976 was especially illustrative of this phenomenon with the identification of the 1976 swine flu virus (H1N1), thought to be a direct descendant of the virus that caused the pandemic of 1918, at a military base in Fort Dix (United States) (Sencer 2011); the identification of *Legionella pneumophila* as the cause of an outbreak of severe respiratory illness among a group of veterans staying at a hotel in downtown Philadelphia (United States), initially feared to be a human outbreak of swine influenza (H1N1) (Centers for Disease Control and Prevention (CDC) 2012a); and the identification of the Ebola virus as the cause of simultaneous outbreaks of haemorrhagic fever in Sudan and the Democratic Republic of Congo (then called Zaire) (CDC 2012b).

Nine years earlier, in 1967, the Marburg virus had been identified for the first time in an outbreak in Germany that caused 25 primary infections and seven deaths among laboratory workers who were infected by handling monkeys from Uganda, and six secondary cases in health workers who took care of primary cases, with subsequent spread to family members (Slenczka and Klenk 2007). A member of the same filovirus family as Ebola, the Marburg virus has caused sporadic small outbreaks in Africa during the 1970s and 1980s, and larger outbreaks in 1998 in the Democratic Republic of Congo and 2005 in Angola. Since the Marburg virus was first identified in 1967 there have been over 40 other newly identified infectious organisms in humans, an average of one per year.

Economic impact of emerging and re-emerging infections

Outbreaks caused by emerging and re-emerging infections are costly (Fig. 8.17.2). They consume healthcare resources and divert them from endemic disease problems, result in productivity loss, and decrease trade and tourism revenue. At times they economically devastate entire sectors. This has occurred after major

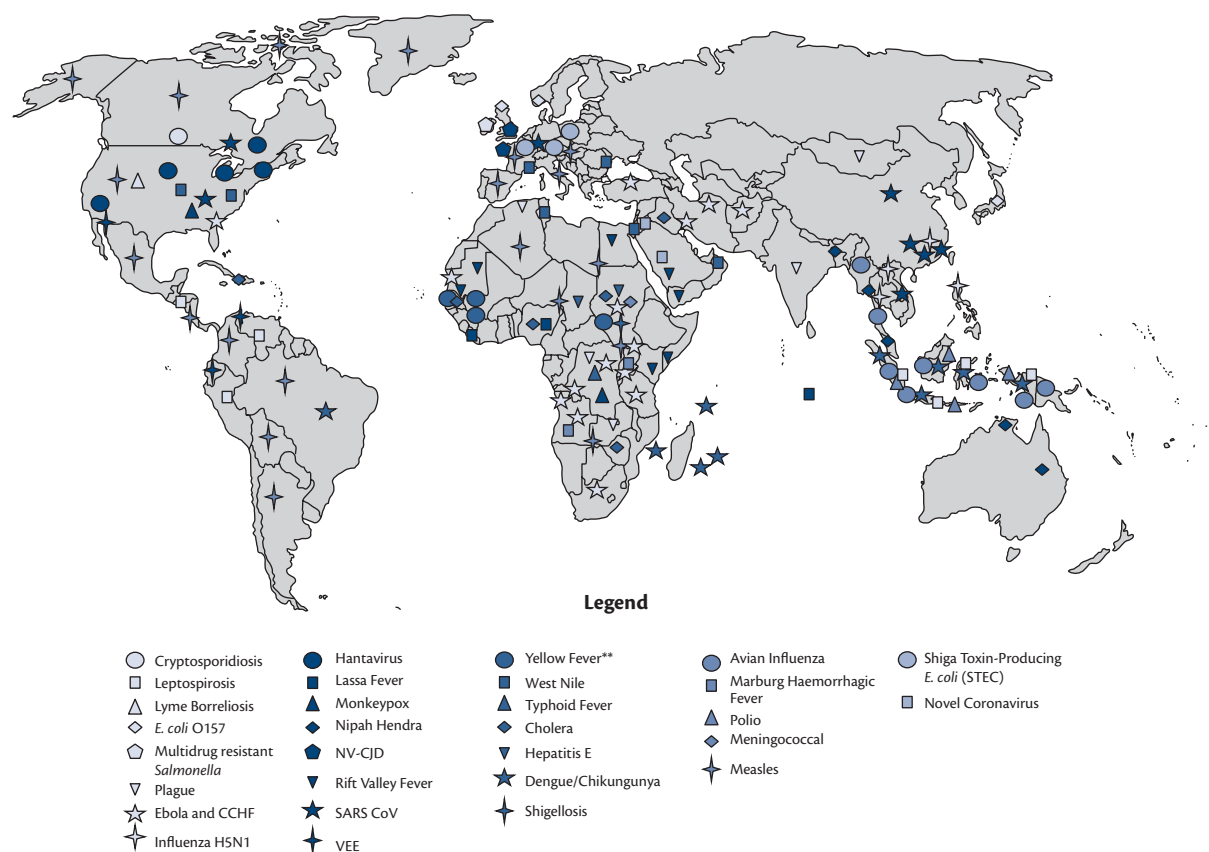

Fig. 8.17.1 Selected emerging and re-emerging infectious diseases, 1996–2012.

outbreaks of emerging or re-emerging infections during the past 20 years, with economic losses ranging from an estimated US\$36 million after the re-emergence of cholera in Tanzania in 1998 (World Health Organization (WHO) 2007a), to approximately US\$39 billion after the emergence of BSE in the United Kingdom during the period 1990–1998 (WHO 2007a). During 2009, after the pandemic of H1N1 had been identified, the Mexican economy lost an estimated US\$2 billion, mainly due to decreased trade and tourism.

Costs from outbreaks can be direct, indirect, or intangible. The most apparent direct costs are those associated with medical care of patients. Indirect costs arise at the individual level from loss of work and caregiving by relatives, and through interventions aimed at reducing the impact of the outbreak such as quarantining of contacts or closure of schools. Indirect costs also arise at the macro-economic level because of their impact on travel, tourism, trade, and consumer confidence. Fear of transmission causes international tourists to choose alternative holiday locations, and local populations to avoid any perceived source of infection such as foods from animals that may have been implicated in the outbreak, restaurants, and other public leisure venues—sectors of the economy that are significant contributors to the gross domestic product (GDP) of many countries. Misinformed consumers avoided purchasing pork during the 2009 pandemic of H1N1 influenza even though it was not a continued source of human infection,

and avoided fresh vegetables during the 2011 outbreak of *Escherichia coli* O104 in Europe when speculation occurred as to its cause. Finally, there are intangible costs such as the loss of life. Economists have attempted to estimate the economic cost of death, but fail to capture other non-economic and socio-cultural changes that can be a consequence of a highly lethal outbreak.

The severe acute respiratory syndrome (SARS) was a good example of an emerging infection with severe indirect costs, as it was responsible for sizeable economic losses and insecurity in financial markets across Asia and worldwide. With fewer than 9000 cases, the outbreak was estimated by the Asian Development Bank to have cost Asian countries an estimated US\$18 billion in GDP terms for 2003, and up to US\$60 billion of gross expenditure and business losses (Asian Development Bank 2003).

In 2008, the World Bank estimated that the cost of a severe influenza pandemic (which would apply to other pandemics of similar severity) could be up to US\$2–3 trillion taking into account healthcare costs and impact on the economy (Burns et al. 2008). It is therefore important to prepare for and respond to infectious disease outbreaks in order to minimize their healthcare and economic impact. Though the economic impact of the 2009 pandemic of H1N1 did not reach these proportions, the H5N1 virus continues to circulate among poultry in Asia with potential to cause a highly lethal and costly pandemic.

Factors influencing emergence and re-emergence

Many external factors may align in such a manner as to provide opportunities for the emergence or re-emergence of infectious diseases. They range from weakened public health infrastructure and failure of safety procedures/regulations to increases in population, anthropogenic activities or climate change, civil disturbance/human displacement, and human behaviour that varies from misperceptions about the seriousness of the risks that cause emerging infections and the use of anti-infective drugs, to the safety of public health interventions and the desire to deliberately cause terror and harm.

Weakened public health infrastructure

Weakening of public health infrastructure resulted in part from decreased investment in public health during the second half of the twentieth century. This is compounded by poverty in lower-resourced countries where there are competing priorities for development, and suboptimal access to healthcare and sanitation. Deficient infrastructure also leads to a lack of the robust public health practices that could prevent the emergence of infectious diseases, or prepare communities to respond to them should they emerge.

Aedes aegypti has now become well established in many large cities worldwide following the deterioration of mosquito control

campaigns during the 1970s. The resurgence of the *Aedes* species has been confounded by the adoption of modern consumer habits in urban areas where discarded household appliances, tyres, plastic food containers, and jars create abundant mosquito breeding sites. With the increase in *Aedes* species there has been an increased risk of dengue outbreaks. Prior to 1970, nine countries, mainly in Latin America, reported outbreaks of dengue. In 1983, 13 countries in Latin America and Asia reported dengue outbreaks, and by 1998, 1.2 million cases were reported from 56 countries. During 2001, 69 countries reported dengue outbreaks, and it is now endemic in more than 100 countries in Africa, the Americas, the Eastern Mediterranean, South East Asia, and the Western Pacific. By 2010, reported dengue infections exceeded 2.2 million annually with more than 20,000 deaths, and estimates place the actual number of infections worldwide at between 50–100 million (WHO 2012a). Major dengue outbreaks have occurred during the past decade in Brazil, Indonesia, Thailand, Vietnam, Bangladesh, India, Pakistan, and Cape Verde. During 2012, an outbreak of dengue occurred in Portugal with 191 probable cases reported (WHO 2012b).

In 2005, the Chikungunya virus, likewise transmitted by *Aedes* species, emerged and spread throughout several southern Pacific islands. A total of 3100 human infections were reported by a sentinel network on La Réunion within the first 6 months of the outbreak, leading to an estimate of over 204,000 human infections by March 2006. In 2007, the Chikungunya virus spread north to Europe, where it caused an outbreak with 292 suspected human

infections in northern Italy, and during 2010–2011 Chikungunya epidemics occurred throughout southern India (WHO 2012c).

Lapses in childhood immunization coverage due to weakened childhood immunization programmes in Russia resulted in the re-emergence of diphtheria, with major epidemics in the early 1990s. Reported cases of diphtheria in the Russian Federation increased from just over 1200 in 1990 to over 5000 in 1993. Likewise, lapses in yellow fever vaccination programmes in sub-Saharan Africa since the 1950s have left large susceptible populations in both rural and urban areas of the region, with sporadic urban outbreaks in cities in Côte d'Ivoire (2001), Senegal and Guinea (2002), and Burkina Faso (2004) (Jamison et al. 2006). This is in contrast to the successful smallpox eradication programme that achieved sustained investment and close links between policy and political support, research, and field programmes that contributed to its success; progress in the eradication of polio that has decreased the annual number of children paralyzed to fewer than 700 in 2011 (WHO 2012d); and the decrease in measles mortality by 74 per cent (2007) since intensified efforts at measles mortality reduction were begun during 2000 (WHO 2008a).

Surveillance systems are critical in the early detection of outbreaks and during their containment, and to monitor progress. Setting up of surveillance systems requires substantial investment in infrastructure and manpower, and the commitment to sustain these systems in the long term. Most epidemiologists recognize that it was in part because of substandard surveillance systems in developing countries that HIV rapidly spread during the late 1970s, and was not detected until it was first identified in the United States in the early 1980s.

Failure of safety procedures/regulations

Substandard universal precautions and hospital regulations during the 1980s led to breaches in sterile injection practices and nosocomial infections of HIV in the former USSR and Romania, together infecting over 250 children, accompanied by high levels of hepatitis B in both patients and health workers (Matic et al. 2006). Likewise substandard universal precautions led to nosocomial outbreaks of Ebola haemorrhagic fever in the Democratic Republic of Congo in 1976 and 1995, where syringes and/or failed barrier nursing amplified the transmission to patients, health workers, and the community (CDC 2012b). Continued lapses in universal precautions led to the amplification of recent outbreaks of Ebola infection in the Democratic Republic of Congo and Uganda, and contributed to nosocomial transmission of SARS in hospitals in China, Hong Kong, Taiwan, Singapore, Vietnam, and Canada where outbreaks then spread to communities.

Blood transfusions are another potential source of infection, especially for emerging infections which are not yet known and therefore impossible to detect by screening. A substantial proportion of HIV cases in the early phases of the epidemic were transmitted by blood transfusion (Curran et al. 1984). Although most countries now test banked blood for HIV and many other known infectious organisms, many resource-poor countries struggle to bank blood and ensure that transfusions are safe (Goodnough et al. 2003).

Changes in the process of rendering the carcasses of ruminant animals for the preparation of bone meal which was fed to other ruminant animals, are thought to have been the cause of the outbreak of BSE in cattle that also led, in May 1995, to the death of

a 19-year-old male in the United Kingdom, the first human death from what is now known to be variant vCJD or human bovine spongiform encephalopathy (hBSE) (Prusiner 1997; Trevitt and Singh 2003). The BSE and hBSE outbreaks demonstrate the health consequences of regulations for rendering that had changed over a 10-year period prior to 1995, inadvertently permitting rendered parts of cattle infected with the BSE-causing prion to contaminate bone meal used for livestock feed. The most likely source of human infection is thought to be through the preparation or consumption of contaminated meat and/or beef products. The BSE and hBSE outbreaks led to the recognition of the need for stronger government intervention along the entire 'feed to food' continuum to better ensure the safety of foodstuffs for human consumption.

Population shifts including rapid increase and uncontrolled urbanization

Population shifts can lead to the emergence, re-emergence, and transmission of infectious diseases. Classic examples are the plague epidemics in Europe in the fourteenth century thought to have originated in Asia and spread first along the Silk Road, then by trade on merchant ships sailing the Mediterranean; and smallpox that is thought to have arrived in the Americas from Europe during the years of exploration and colonization that began in the fifteenth century. These epidemics incited fear and killed many who became infected, threatening to bring down entire civilizations. The world is much more easily travelled and interconnected since then, with large numbers of people moving from continent to continent every day. This has facilitated the international spread of emerging diseases as illustrated by the SARS epidemic that spread from a medical doctor who had treated patients with a severe atypical pneumonia in Guangdong Province, China. He became ill, but travelled to Hong Kong for a wedding and spent a night in a hotel where he somehow passed the infection to tourists and other travellers who then seeded outbreaks in Vietnam, Singapore, Canada, and other parts of the world within days.

Population growth can result in increased disease transmission, especially where the infrastructure is unable to cope. The world's population more than doubled in the second half of the twentieth century, accelerating most rapidly in the developing countries of the tropics and subtropics. Rural–urban migration has resulted in crowded living conditions, and inadequacy of water and sanitation systems, and other basic infrastructure. In 1950, there were two urban areas in the world with populations greater than 7 million; by 1990, this number had risen to 23. In 2012, as urban migration continues, there are 25 megacities, each with more than 10 million people.

Population increases in Latin America resulted in breakdowns in sanitation and water systems in large coastal cities. In 1991, when cholera re-emerged in Peru after having been quiescent for approximately 100 years, it rapidly spread throughout other urban areas in Latin America. Thought to have originated from contaminated seafood on the Peruvian coast, the disease caused nearly 400,000 reported cases and over 4000 deaths in 16 South American countries that year. By 1995, there were more than 700,000 reported cases and just over 6000 deaths in the Americas, and in 2012, cholera remains endemic in many areas (Delgado et al. 2011).

Uncontrolled urbanization, with overcrowding and substandard living conditions in slum areas of Asia and Africa, has likewise

contributed to the re-emergence of tuberculosis (TB) and plague. HIV infection, also concentrated in urban areas, has facilitated the re-emergence of TB, showing the sometimes dynamic interaction among infectious agents. The most recent serious outbreak of plague occurred in five states in India in 1994, where almost 700 suspected bubonic or pneumonic plague cases and 56 deaths were reported; a smaller outbreak of 16 persons with pneumonic plague was reported from northern India in 2002 (Gupta and Sharma, 2007).

Anthropogenic activities or climate change

Deforestation that disrupts natural habitats of animals, and forces animals, searching for food, into closer contact with humans has been linked to the emergence and re-emergence of Lassa Fever in West Africa, and sine nombre virus in North America. First identified in 1969 when two nurses died with a haemorrhagic fever syndrome in Nigeria, the Lassa Fever virus is now known to be transmitted to humans from human food supplies and/or the household environment contaminated by urine and/or other excreta of infected rodents (Fichet-Calvet and Rogers 2009; Senior 2009). In many instances, rats invade human living spaces in search of food because rainforests, a natural habitat, have been destroyed. Sin nombre virus is a hantavirus, first identified in an outbreak in the southwestern United States in 1993. It is now known to spread from infected rodents to humans through aerosolized excreta found in dust of homes that have been invaded by rodents (CDC 2012c).

The Nipah virus outbreaks in Malaysia and Singapore in 1998–1999 are another example where evidence suggests that anthropogenic activities, including clearing of forests for agricultural purposes, encroached on the natural reservoir for the Nipah virus, the fruit bat. The virus, excreted in bat guano, is thought to have infected pigs that were farmed in areas that had penetrated the forests. The virus subsequently spread to humans in close contact with the infected pigs, and resulted in outbreaks with approximately 250 human infections and 100 deaths from Nipah-caused viral encephalitis. Additional outbreaks of the Nipah virus from 2001 to 2009 in Bangladesh suggested indirect transmission from bats to humans through palm wine collected from palm trees where fruit bats are known to feed, and direct human-to-human transmission in hospitals (Epstein et al. 2006). Another virus thought to be carried by bats, the Ebola Reston virus, infected pigs in the Philippines in 2009, and the virus spread from pigs to pig farmers and workers in slaughterhouses causing asymptomatic infection (Miranda and Miranda 2011).

In Latin America, Chagas disease re-emerged as an important human disease after deforestation caused triatomine populations to move from their wild natural hosts to involve humans and domestic animals in the transmission cycle, eventually transforming the disease into an urban infection that can also be transmitted by blood transfusion. Other emerging infections influenced by changing habitats of animals include Lyme borreliosis in Europe and North America, transmitted to humans who come into contact with ticks that normally feed on rodents and deer, the natural reservoir of *Borrelia burgdorferi*.

Climatic changes, both anthropogenic and from natural variations, also influence the development of epidemics. The narrow band of desert in sub-Saharan Africa, in which epidemic *Neisseria meningitidis* infections traditionally occur, has enlarged as

drought spread south to involve Uganda and Tanzania. Climate extremes, whether involving excessive rainfall or drought, can likewise displace animal species and bring them into closer contact with human settlements, or increase vector breeding sites. A 1998 outbreak of Japanese encephalitis in Papua New Guinea has been linked to extensive drought, which led to increased breeding sites for the *Culex* mosquito as rivers dried into stagnant pools (Erlanger et al. 2009). It is thought that mosquitoes then transmitted the Japanese encephalitis virus from infected pigs and/or wild birds to humans. The Japanese encephalitis virus is now widespread in Southern Asia from India and Thailand to Malaysia, and as far north as Korea and Japan.

Above-normal rainfall associated with the occurrence of the warm phase of the El Niño Southern Oscillation phenomenon is thought to have been the cause of extensive flooding in East Africa from December 1997 to March 1998, increasing the breeding sites for *Aedes* mosquitoes. Mosquitoes then facilitated the transfer of the Rift Valley fever (RVF) virus from infected cattle, sheep, and/or goats to humans who had been forced to live in close proximity to animals on islands of dry land surrounded by flood water. During this period, the largest RVF outbreak ever reported in East Africa occurred in Kenya, Somalia, and Tanzania. The total number of human infections in northern Kenya and southern Somalia alone was estimated at 89,000 with an estimated 478 deaths. During 2006 and 2007, RVF caused outbreaks with approximately 250 human infections and 130 deaths in Kenya, Somalia and Sudan; and an outbreak of 172 cases and 15 deaths occurred in 2010 in South Africa (Hightower et al. 2012).

Public health consequences of civil disturbance, human displacement, and natural disasters

Human population movements on a large scale as a result of war, conflict, or natural catastrophe often result in crowded, unhygienic, and impoverished living conditions. This in turn heightens the risk of emergence and re-emergence of infectious diseases. In the aftermath of civil disturbance in Rwanda in 1994, over 48,000 cases of cholera and 23,800 deaths were reported within 1 month among Rwandans who had been displaced to refugee camps in Goma, Democratic Republic of Congo (Goma Epidemiology Group, 1995).

A collateral impact of war, conflict, or natural catastrophe such as earthquakes is the destruction or weakening of health systems with diminished capacity to detect, prevent, and respond to infectious disease outbreaks. One consequence of the 27-year civil war in Angola was the outbreak of Marburg haemorrhagic fever in 2004 that spread to more than 200 humans, 90 per cent of whom died. Emergence of the Marburg virus was detected late and transmission was amplified in overcrowded and understaffed health facilities where lack of investment during the war had resulted in substandard infection control. Another large outbreak of Marburg virus infection was identified in late 1998 in the Democratic Republic of Congo, also a conflict-ravaged country. This emergence resulted in sporadic cases with small chains of transmission over a 2-year period in a remote area where civil war had interrupted supply lines and communication to health facilities in the region (Bausch et al. 2006).

Natural disasters can also create conditions that facilitate the direct or indirect spread of infectious disease. Flooding commonly disrupts clean water supplies, and in 2009 in the Philippines,

where leptospirosis is endemic, more than 2000 reported human infections, with an estimated case fatality rate of 10 per cent, were associated with flooding caused by a major typhoon (Amilasan et al. 2012). The deterioration of clean water supplies and health services in Haiti after a major earthquake in 2010 served as fertile ground for a cholera importation that led to an outbreak of approximately 600,000 infections and 7500 deaths, approximately 6 per cent of the entire post-earthquake population (CDC 2012d; Piarroux and Faucher 2012).

Human behaviour

Occupation

Throughout history, some human occupations have been associated with infectious disease. Anthrax has been called wool-sorters' disease because of transmission of its spores from infected animals to humans who shear sheep and other wool-producing animals, or whose occupation leads to exposure to their hides. It has also been associated with butchers who come into contact with infected animals at the time of slaughter or during preparation of meat for markets. Anthrax spores infect humans either intra-dermally, causing cutaneous anthrax, or by ingestion or inhalation, causing enteric or pulmonary/inhalation anthrax.

Though intensive research has failed to confirm the origins of Ebola haemorrhagic fever outbreaks, infection is thought to occur as humans encounter animal sources, possibly infected bats and/or non-human primates infected by bats, somewhere in the transmission cycle. An outbreak of Ebola haemorrhagic fever in humans in 1995 was linked to a woodsman, who worked deep within the tropical rainforest making charcoal, where he was believed to have become infected with the Ebola virus that he then carried back to his home village. An outbreak of Ebola in Gabon in 1996 is thought to have had a point source in a chimpanzee that was killed and butchered by a group of young hunters; and in 1994 a Swiss researcher infected with the Ebola virus in a forest reserve in West Africa is thought to have become infected while conducting chimpanzee autopsies in search of the cause of a major die-out of the animals (Daszak 2006). A more recent outbreak of Ebola in Uganda has been associated with exposure to bat guano in gold mines in 2008 (Food and Agricultural Organisation 2011).

In 2003, a veterinarian in the Netherlands became infected with the influenza A (H7N7) virus during an investigation of influenza outbreaks in poultry and later died from acute respiratory failure. A total of 89 humans, including the veterinarian, were confirmed to have H7N7 influenza virus infection linked to this poultry outbreak and no further deaths occurred. The majority of human infections are thought to have occurred as a result of direct contact with infected poultry; but there were three possible instances of transmission of infection from poultry workers to family members (Jong et al. 2009). The H5N1 influenza virus has caused major lethal epidemics of influenza among poultry in many Asian countries, and exposure of children or adults to infected poultry being raised in backyards or industrial poultry farms has resulted in periodic human infections. By August 2012, a total of 608 sporadic infections had been reported to the WHO with an estimated case fatality rate of approximately 59 per cent (WHO 2012e). Several countries have reported small clusters of persons infected with H5N1 infection that do not sustain transmission, usually occurring in family members or others who have close contact with an infected person.

Healthcare workers are exposed to emerging and re-emerging infections on two fronts. Laboratory and health workers are at especially high risk of emerging and re-emerging infections, and can themselves be conduits of transmission. In the 1995 outbreak of Ebola haemorrhagic fever in Kikwit (Democratic Republic of Congo), almost one-third of those infected were health workers, and in the 2003 SARS outbreak in Singapore, ten health workers were thought to have been infected while treating an infected health worker colleague who is also thought to have infected her husband, three other patients, and seven visitors to the hospital (Wilder-Smith et al. 2005). These examples show the potential for health workers to become infected, and in some instances to sustain and amplify transmission in hospitals, and through their patients and family members, to the community. Laboratory workers are also at risk of infection: the last human case of smallpox was caused by a laboratory accident in the United Kingdom, and the last-known human cases of SARS occurred in laboratory accidents in Singapore and China.

Mistrust and misinformation

During 2003, unsubstantiated rumours circulated in northern Nigeria that the oral polio vaccine (OPV) was unsafe and vaccination of young children could cause infertility. Mistrust and misinformation that followed led to the government-ordered suspension of polio immunization in two northern states and substantial reductions in polio immunization coverage in those states, and a large number of others (Larson and Heymann 2010). The result was a polio outbreak across northern Nigeria that then spread to, and re-emerged in, previously polio-free areas in sub-Saharan Africa, the Middle East, and as far as Indonesia. Over 70 per cent of all children worldwide who were paralysed by polio during the following year, 2004, were living in Nigeria—or in other parts of sub-Saharan Africa that had been re-infected by polio virus genetically linked to viruses that had a Nigerian origin (United Nations Children's Fund 2006; Modlin 2010).

Misinformation about the safety of vaccines against pertussis, measles, and hepatitis B has likewise led to decreases in vaccine uptake among children, and in some instances industrialized country outbreaks of pertussis and measles. An example is a decrease in uptake of the measles, mumps and rubella (MMR) vaccine in the United Kingdom from a coverage of 92 per cent at the time of a falsified publication in 1998 that suggested a link between MMR and autism, to a low of 79 per cent during 2003 (Pearce et al. 2008). To ensure vaccine uptake is maximized, public confidence in the benefit, safety, and effectiveness of vaccines must be upheld, which in turn, relies on a comprehensive evidence base underpinning vaccination strategies (Larson et al. 2011).

Deliberate use to cause terror and harm

Infectious organisms have been deliberately used to cause terror and harm throughout history, with accounts of the use of highly infectious and lethal organisms such as smallpox to kill or weaken the opposition during wars in the eighteenth century (Riedel 2005), and this has continued into the twenty-first century. It was graphically illustrated in 1979 in an outbreak of inhalation anthrax in Sverdlovsk, 1400 km east of Moscow, in the then Soviet Union. Attributed at first by government officials to the consumption of contaminated meat, it was later shown to have been caused by

the unintentional release of anthrax spores from a Soviet military microbiology facility. It is estimated that up to 358 humans were infected and that between 45 and 199 died (Meselson et al. 1994) (see Chapter 8.18).

In the United States in late September 2001, the deliberate dissemination of anthrax spores in four known letters sent through the United States Postal Service caused massive disruption of postal services in the United States, and in many other countries around the world. The anthrax letters—dated 11 September 2001, and postmarked 7 days later—caused huge public alarm and prompted a massive public health response. A total of 22 persons are thought to have been infected by anthrax spores sent through the postal system; 11 developed cutaneous anthrax and the remaining 11 developed inhalation anthrax, of whom five died. Twenty of the 22 patients were exposed to work sites that were found to be contaminated with anthrax spores. Nine of them had worked in mail processing facilities through which the anthrax letters had passed (Bouzianas 2009).

Other bacteria, viruses, mycotic organisms, and biological toxins are also considered to have the potential for deliberate use to cause harm to humans. Great concern has been expressed by many countries about the potential health consequences that could be caused by the deliberate introduction of infectious organisms such as the variola virus into a human population where smallpox vaccination is no longer practised, or the plague bacillus that could potentially cause an outbreak of pneumonic plague. Stockpiles for vaccines against infections such as smallpox and anthrax are currently being maintained, at great expense, as part of emergency contingency planning in some countries.

In addition to the deliberate use of existing infectious agents, new laboratory research can result in the creation of novel agents that have the potential for human spread. One example is the laboratory research on H5N1 influenza viruses to determine the mutations that will facilitate human spread. While the research was performed to understand the determinants of transmission in an academic setting, if these more transmissible viruses were to fall into the wrong hands, it could result in a pandemic of unprecedented proportions. This has resulted in much debate among the scientific and regulatory communities on the merits of research with potential dual uses.

Antimicrobial drug resistance—susceptibility of infectious organisms to anti-infective drugs

Bacteria, viruses, and parasites all have the potential to develop resistance to anti-infective drugs by spontaneous mutation and natural selection, or through the exchange of genetic material between strains and species. These resistant organisms can then transmit from human to human, replacing more susceptible organisms with resistant strains. Soon after development of the first antibiotics, warning signs of microbial resilience began to appear. By the end of the 1940s, resistance of hospital strains of *Staphylococcus aureus* to penicillin emerged in the United Kingdom with levels as high as 14 per cent, and by the end of the 1990s, levels had risen to of 95 per cent or greater. Resistance has also developed to semi-synthetic penicillin derivatives as *S. aureus* has acquired genes encoding resistance to methicillin and other narrow-spectrum beta-lactamase-resistant antibiotics. Methicillin-resistant *S. aureus* (MRSA), first identified

in the United Kingdom in 1961 within a year of the introduction of methicillin, is now widespread in hospital-acquired infections in the United Kingdom and throughout the world (Johnson 2011).

The bacterial and viral infections that contribute most to human disease are also those in which antimicrobial resistance is rapidly emerging: diarrhoeal diseases such as dysentery; respiratory tract infections, including pneumococcal pneumonia and TB; sexually transmitted infections such as gonorrhoea and HIV; and infectious organisms that have now accumulated resistance genes to virtually all currently available anti-infective drugs such as extremely drug-resistant TB (XDR-TB).

Since 2008, Gram-negative Enterobacteriaceae have been shown to be resistant to a broad range of beta-lactam antibiotics including carbapenems that are widely used for their treatment. Carbapenem-resistant bacterial infections have been identified in many countries across the world with emergence thought to have occurred somewhere in Asia (Kumarasamy et al. 2010).

The causes of antimicrobial drug resistance (AMR) are complex, and involve both the human and animal health sectors, and others such as plant and fish agriculture. AMR is a major global public health issue because it threatens the effectiveness of antimicrobials in combating infection, which has been one of the most important advances in clinical medicine. A lack of effective antimicrobials could lead the world back to the pre-antimicrobial era where simple infections often led to severe outcomes, and where effective measures to control the spread of disease, especially those for which there are no vaccines, would be lost. AMR also increases healthcare and other indirect costs as more expensive treatments are required, and illnesses may be prolonged.

Use of anti-infective drugs in human health

Behaviours such as over- or under-prescribing of antibiotics by health workers, excessive demand for antibiotics by the general population, or the use of substandard drugs with inferior anti-infective drug content, have had a remarkable impact on the selection and survival of resistant microbes, rapidly increasing levels of microbial resistance.

In Thailand, among 307 hospitalized patients in the late 1980s, 36 per cent of persons who were treated with anti-infective drugs did not have an infectious disease (Aswapokee 1990). Over-prescribing of anti-infective drugs occurs in most other countries as well. In Canada, it has been estimated of the more than 26 million people treated with anti-infective drugs, up to 50 per cent were treated inappropriately (Kondro 1997). This has also led to community-based resistance where otherwise healthy individuals may be carrying resistant microbes which can result in transmission or infection. Findings from community surveys of *Escherichia coli* in the stool samples of healthy children in China, Venezuela, and the United States suggest that although multiresistant strains were present in each country, they were more widespread in Venezuela and China, countries where less control is maintained over antibiotic prescribing and sales (Lester et al. 1990).

The availability of multiple drugs to treat TB since the 1940s has reduced death rates from TB substantially. Resistant organisms have emerged, however, facilitated by inappropriate prescribing and poor adherence to treatment regimes. Multi-drug resistant TB (MDR-TB) has now become widespread, especially in prison settings in Eastern Europe, and resistant organisms are now

being transmitted to healthy populations throughout the world. In 2006, an outbreak of extremely drug-resistant TB (XDR-TB), against which almost all TB drugs are ineffective, occurred in South Africa (WHO 2012f), and all XDR-TB cases that were tested for HIV were found to be HIV-positive as well. To date, more than 60 countries have reported XDR-TB (WHO 2011), and with HIV infection endemic, the world provides continued fertile ground for the transmission of all forms of TB, including MDR- and XDR-TB.

Malaria is another major infection with high mortality that has been reduced substantially with the introduction of antimalarial drugs. By 1976, however, chloroquine-resistant *Plasmodium falciparum* malaria had developed and was highly prevalent in South East Asia. Ten years later, chloroquine-resistant malaria was found worldwide, as was high-level resistance to two second-line drugs, sulphadoxine/pyrimethamine and mefloquine. Subsequently, use of artemisinin combination therapy is now recommended by the WHO to ensure effective treatment, but since 2009 there are reports of artemisinin resistance in South East Asia, threatening to derail efforts to control malaria in Asia, and worldwide (Nayyar et al. 2012).

Prevention and control of resistant infections such as MRSA and *Clostridium difficile* in healthcare facilities is an important key to reducing the spread of AMR, and control of such hospital-acquired infections must be a priority.

Use of anti-infective drugs in animal husbandry and agriculture

Large quantities of anti-infective drugs are indiscriminately added to animal feed in some countries to promote animal growth, resulting in the selection of resistant bacterial strains in animals. Antibiotics are also used in agriculture for spraying of fruit trees, rice paddies, and flowers to avoid bacterial blights.

Some of the organisms that infect animals freely circulate between animals and humans, providing opportunities for zoonotic infection with resistant organisms, and for swapping or exchanging resistant genes, thus increasing the speed with which anti-infective resistance evolves in both agriculture and human populations. Alternative approaches can reduce such antibiotic use as in Norway, where the introduction of effective vaccines in farmed salmon and trout, and improved health management, reduced the annual anti-infective use in farmed fish by 98 per cent from 1987 to 2004 (WHO 2012g). During the 1990s, Norway and other countries throughout Europe banned the non-discriminate use of antibiotics for growth promotion in animal feed.

The weakness of surveillance and monitoring systems for antimicrobial resistance, partially the result of the lack of easy-to-use surveillance tools, makes it difficult to understand the extent and evolution of the AMR problem globally. The lack of financial investment for research into new antimicrobials and vaccines is also a major global problem. Many of the anti-infective drugs currently in use were developed decades ago and the lack of drugs that target non-similar areas on microbes limits treatment modalities available to combat infections.

The WHO has proposed a five-pronged containment strategy for AMR (Fig. 8.17.3), the implementation of which is being promoted worldwide through activities set up around a World Health Day in 2011, and a report on AMR in 2012. Underpinning

Fig. 8.17.3 The five key areas for containment of antimicrobial resistance.

Source: data from World Health Organization (WHO), *Model based on the WHO Global Strategy for Containment of Antimicrobial Resistance*, Copyright © WHO 2001, available from http://www.who.int/csr/resources/publications/drugresist/en/EGlobal_Strat.pdf.

this strategy is the need for national commitments for sufficient and sustainable resources to be made available to combat AMR (WHO 2012h).

Public health security: globalization and emerging/re-emerging infectious disease organisms

Our world of increased human mobility and interdependence facilitates the transfer of infectious organisms from country to country, and across continents. Infectious organisms efficiently travel in humans, insects, food, and animals, and can spread around the globe and emerge in new geographic areas with ease and speed. Some are transported by migratory birds. Others, such as disease-carrying mosquitoes, travel in the passenger cabin or luggage hold of jets, to cause tropical infections in temperate countries when they feed on airport workers or those who live nearby. They thus threaten public health security—our collective vulnerability to acute infectious disease outbreaks across international borders (Heymann 2003).

In 2000, among 312 athletes participating in an international triathlon held in Malaysia, 33 became infected with leptospirosis and returned to their home countries during the incubation period. While leptospirosis lacks human transmissibility and therefore did not set up local foci or transmission, the outbreak of SARS in 2003 clearly did, and demonstrates the full potential of emerging infectious organisms to spread internationally. From a medical doctor infected in Guangdong Province of China, who unknowingly carried the new infectious organism to a Hong Kong hotel, SARS spread in individual chains of transmission from infected hotel guests to 8422 reported cases in North and South America, the Middle East, Europe, and Asia with a case-fatality rate of approximately 11 per cent (WHO 2003).

During the years 1969–2003, 18 instances of airport malaria were reported to the WHO—malaria infections in workers at airports or in persons who live nearby who had not travelled to malaria-endemic countries (WHO 2007b). Their infection originated from malaria-infected *Anopheles* mosquitoes that had travelled from countries with endemic malaria and took a blood meal from airport workers or other persons upon landing. In 2003, a seven-person outbreak of malaria among persons in Florida who

had not previously travelled to malarious areas demonstrated the potential for imported malaria to set up local foci of transmission if the *Anopheles* mosquito is present (Morbidity and Mortality Weekly Report 2004).

Livestock, animal products, and food can also carry infectious organisms that emerge or re-emerge in non-endemic countries. VCJD, identified in persons in 11 countries, most of whom had not previously travelled to the United Kingdom (Diack et al. 2012), clearly demonstrates the ability of infections to travel in animals or animal products. RVF emerged in humans in Yemen and Saudi Arabia in 2000, 2 years after a major outbreak of RVF in East Africa. Infection has since become endemic in livestock in the Arabian Peninsula, and is thought to have been imported from East Africa in livestock traded across the Red Sea (Balkhy and Memish 2003). In 2000, imported raspberries contaminated with *Cyclospora* caused an outbreak in the United States. It is hypothesized that the raspberries imported from Guatemala were contaminated when surface water was used to spray them with fungicide before harvest (Ho et al. 2002). In 2011, an outbreak caused by *Escherichia coli* O104 linked to sprouts grown from imported beans resulted in over 3000 infections and 31 deaths from haemolytic uramic syndrome (European Food Safety Authority 2012).

Concerns about the international spread of emerging and re-emerging infections and the need for strong public health security are not new. By the fourteenth century, governments had recognized the capacity for international disease transmission and legislated preventive measures, as reflected in the establishment of quarantine in the city state of Venice. Arriving ships were not permitted to dock for 40 days, and people at land borders were held in isolation for 40 days in the hope of keeping plague from entering.

Many European leaders of the mid-nineteenth century, worried by the cholera pandemic of the time, threats of plague, and the weakness of quarantine measures, began to recognize that controlling the spread of infectious diseases from one nation to another required cooperation between those nations. International conventions were organized and draft covenants signed, almost all of which related to some type of quarantine regulations.

From 1851 to 1897, ten international sanitary conferences were held among a group of 12 European countries, focusing exclusively on the containment of epidemics in their territories. The inaugural 1851 conference in Paris lasted 6 months and was followed in 1892 by the first International Sanitary Convention that dealt with cholera. Five years later, at the 10th International Sanitary Conference, a similar convention that focused on plague was signed.

New policies then emerged in the late nineteenth century, such as the obligatory telegraphic notification of first cases of cholera and plague, a model that a small group of South American nations followed when they signed the first set of international public health agreements in the Americas during the 1880s. In addition to cholera and plague, often carried by immigrants arriving from Europe, the agreements in the Americas covered yellow fever that was endemic in much of the American region at that time, and that from time to time caused major urban epidemics.

During the following decade, 12 countries attended the First International Sanitary Convention of the American Republics in Washington, DC, leading to the creation of the Pan American Sanitary Bureau (now called the Pan American Health Organization) in 1902. Its counterpart in Europe was the Office

International d'Hygiène Publique (OIHP), established in 1907, and based in Paris.

In 1951, 3 years after its founding, the WHO adopted a revised version of the International Sanitary Regulations (1892) that remained focused on the control of cholera, plague, and yellow fever and was rooted firmly in the preceding agreements of the nineteenth and twentieth centuries.

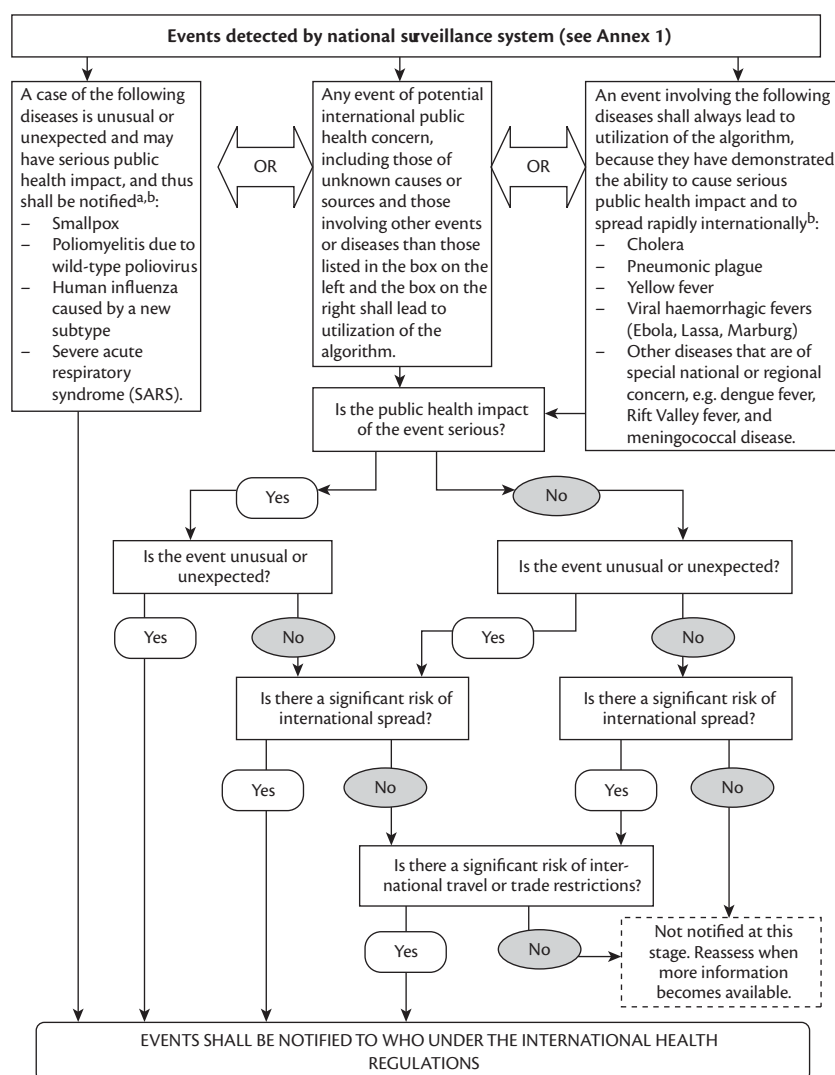

The International Health Regulations

In 1969, the Member States of the WHO agreed to a new set of international sanitary regulations—the International Health Regulations (IHR)—aimed at better ensuring public health security with minimal interruption in travel and trade. In addition to requiring reporting of four infectious diseases—cholera, plague, yellow fever, and smallpox—the IHR were aimed at stopping the spread of disease by pre-established control measures at international borders. They included reporting requirements for these four diseases, and described appropriate responses such as yellow fever and smallpox vaccination for passengers arriving from countries where yellow fever or smallpox outbreaks had been reported. The IHR provided a legal framework for global surveillance and control of spread of infectious diseases.

By 1996, it had become clear, however, that the IHR were not able to ensure public health security as had been envisioned. Over the previous 30 years, border posts proved inadequate to stopping the international spread of infectious diseases which often crossed borders while still in the incubation period in humans, or silently in non-human hosts—insects, animals, food, and agriculture goods. At the same time, countries reported the occurrence of cholera, plague, and yellow fever late or not at all because of fear of stigmatization and economic repercussions (smallpox had been removed from the list when it was certified eradicated in 1980). The IHR also did not meet the challenges caused by other emerging and re-emerging infectious disease and their rapid transit round the globe.

From 1996 until 2005, WHO Member States therefore undertook a process to examine and revise the IHR. The result—the IHR (2005) (WHO 2008b)—provided a more up-to-date legal framework requiring reporting of any public health emergency of international concern (PHEIC), and the use of real-time evidence to recommend measures to stop their international spread. A PHEIC is defined as an extraordinary event that could spread internationally or might require a coordinated international response (WHO 2012i). Under the IHR (2005) an event is evaluated for its potential to become a PHEIC by the country in which it is occurring even though reporting might legitimately come from elsewhere, using a decision tree instrument developed for this purpose (Fig. 8.17.4). If the criteria for a PHEIC are met, an official notification must be provided to the WHO. Notification is also required for even a single occurrence of a disease that would always threaten global public health security—smallpox, poliomyelitis caused by a wild-type poliovirus, human influenza caused by a new virus subtype, and SARS. In addition, there is a second list that includes diseases of documented—but not inevitable—international impact. An event involving a disease on this second list, which includes cholera, pneumonic plague, yellow fever, Ebola, and the other haemorrhagic fevers, still requires the use of the decision tree instrument to determine if it is a PHEIC. Thus, two safeguards create a baseline

ANNEX 2
DECISION INSTRUMENT FOR THE ASSESSMENT AND NOTIFICATION OF EVENTS THAT MAY
CONSTITUTE A PUBLIC HEALTH EMERGENCY OF INTERNATIONAL CONCERN

^a As per WHO case definitions.

^b The disease list shall be used only for the purpose of these Regulations.

Fig. 8.17.4 Decision tree for assessment of a potential public health event of international concern.

of public health security by requiring countries to respond, in designated ways, to well-known threats.

In contrast to previous regulations, the IHR (2005) introduced a set of core capacity requirements for surveillance and response. All countries were to meet these requirements during the first 5 years of implementation of the IHR (2005) in order to rapidly detect, assess, notify, report, and contain the events covered by the regulations so that their potential for international spread and negative economic impact would be minimized. The IHR (2005) likewise require collective action by all WHO Member States in the event that an emerging or re-emerging infectious disease threatens to spread internationally, and the free sharing of information pertaining to this threat. They thus provide a safety net against

the international spread of emerging or re-emerging infections, requiring collaboration between all states to ensure the timely availability of surveillance information and technical resources that better guarantee international public health security.

Other international frameworks have also been developed to contain and curtail the international spread of emerging infections. Among them are the WHO Global Strategy for the Containment of Antimicrobial Resistance (WHO 2001a) described earlier in this chapter (see 'Use of anti-infective drugs in animal husbandry and agriculture'). Though not legally binding, this framework calls on countries to work across the human health, animal health, agricultural, and trade sectors to ensure more rational use of anti-infective drugs in order to limit the factors that accelerate

the selection and proliferation of anti-infective drug-resistant microbes.

Recommendations for the future

National and international systems for addressing the threat of infectious diseases

To enable the world to deal effectively with the threat of emerging and re-emerging diseases, there is the need for countries to follow the international frameworks laid out by such agreements as the International Health Regulations (2005) and the WHO Global Strategy for the Containment of Antimicrobial Resistance (2001a); and also by the United Nations Framework Convention on Climate Change, still under negotiation. These international agreements call for action at the global, national, and subnational levels that will decrease the risks factors that influence emergence and re-emergence of infectious diseases. At the same time, if followed they will result in better detection and response where and when emerging and re-emerging public health events occur, be they at the animal/human interface or in other situations where a series of risk factors align in such a way as to permit their occurrence. Effectively preventing, or rapidly detecting, assessing, and responding to infectious disease outbreaks will save lives and protect economies.

The link between health and overall human development is also important, as many factors such as poverty, lack of education, and basic community infrastructure play a role in emergence and re-emergence. As concluded by the WHO Commission on Macroeconomics and Health (2001b), health considerations must be placed squarely at the centre of economic development, and all sectors of society must work together to achieve this goal, as it is not the sole purview of the health sector alone.

A better understanding of our ecosystem and causative factors will enable preventive actions that reduce the likelihood of disease emergence, especially infections at the animal/human interface. One example is safe and healthy market programmes to encourage proper handling and distribution of livestock and maintenance of strict sanitation in markets where animals or animal products are sold that could be a source of infection.

For emerging and re-emerging infections that are able to transmit from person to person, the window of opportunity for effective intervention often closes quickly. The most important defence against their international spread is robust surveillance and preparedness, response protocols, and mitigation systems. This includes highly sensitive national surveillance systems, public health laboratories that can rapidly detect such outbreaks, and mechanisms for timely outbreak containment and mitigation. It also necessitates good communications systems, and risk communication and health education programmes, to enable coordinated preparedness and response by all stakeholders. These are the core capacities required by the IHR (2005), and it is clear that the same systems that detect and contain naturally occurring outbreaks also permit detection and initial response to deliberately caused outbreaks of infectious disease.

The collaborative action required by IHR (2005) when emerging or re-emerging infections threaten to spread internationally likewise provides a framework for global surveillance and response that is a departure from previous international

conventions and regulations. The IHR (2005) explicitly acknowledge that non-state sources of information about outbreaks often precede official notification, especially when countries may be reluctant to reveal an event in their territories. Collaboration among countries for public health security in the face of emerging and re-emerging infections is vital. If an outbreak of emerging or re-emerging infectious disease occurs in a country that requires international assistance to help in containment activities, as agreed by the WHO and the affected country after confidential and pro-active consultation, other countries are obligated to provide the technical expertise required to the country through WHO or bilaterally. To this end, global databases of professionals with expertise in specific diseases or epidemiological techniques are maintained as part of the requirement of the IHR (2005), together with non-governmental organizations present in countries and in a position to reach remote areas. Such mechanisms, which are further supported by the WHO network of Collaborating Centres (national laboratories and institutes throughout the world serving as international reference centres), help optimize the use of global expertise and resources. The IHR (2005) were instrumental in the coordination of the international response to the H1N1 influenza pandemic in 2009. Upon the recommendation of the IHR Emergency Committee set up by the Director General of the WHO, the pandemic was declared within weeks of its onset, and triggered a series of obligations for collaboration among countries under the IHR (2005). Operational protocols that had been developed as part of pandemic planning and preparedness activities in countries around the world were implemented, together with coordinated actions under the IHR (2005).

The future

The vision embraced by the IHR (2005) is of a world alert and ready to respond collectively to the threat of emerging and re-emerging infections that represent an acute threat to public health security. This requires an unbroken line of defence within countries and globally, using the most up-to-date technologies of surveillance and response.

The IHR (2005) require adherence to new norms and standards for reporting and responding to emerging and re-emerging infections despite the economic consequences that may result. Their full achievement will provide the highest level of public health security possible. National core capacities as described in the IHR (2005) must be put in place within the national public health system that can detect, investigate, communicate, and contain events that threaten public health security as soon as they appear. An interconnected system must be operating at the national and international levels, engaged in specific threat and risk assessment and management activities that minimize collective vulnerability to public health events.

These two goals are interdependent and must be sustained. They involve measures that the international community must continually invest in, strive to achieve, and assess for progress. In today's mobile, interdependent, and interconnected world, threats arising from emerging and epidemic-prone diseases affect all countries. Such threats reinforce the need for shared responsibility and collective action in the face of universal vulnerability, in sectors that go well beyond health.

Bioterrorism

Nicholas S. Kelley and Michael T. Osterholm

History of biological warfare and terrorism

Since antiquity, those in conflict have sought ways to increase their chance of victory. As early as 1320 BC, infectious diseases were used as weapons during wars (Trevisanato 2007). Plague-infested bodies were catapulted over the fortified walls of Caffa (now Feodosiya, Ukraine) by the Tartar army in 1346 (Wheelis 2002). Clothing and blankets contaminated with variola virus, the causative agent of smallpox, were provided to native Indian populations in North and South America from the sixteenth to the eighteenth centuries. While in most cases these devastating infections were not intentionally transmitted, their occurrence made resistance to hostile troops difficult. The Delaware Indians, in contrast, were deliberately infected with variola, which resulted in a smallpox outbreak that allowed the British to take a contested fort due to the reduced numbers of Delaware defending the fort. The Continental Army, fighting for independence from the British, were variolated (an early version of smallpox vaccination) in 1777 to help protect the troops from outbreaks of smallpox that had devastated the army and to minimize the impact of intentional spread of smallpox by loyal colonists (Dembek 2011).

The First World War saw limited use of biological warfare agents. Biological warfare is defined as the intentional release of a biological agent(s) or toxin(s) to incapacitate or kill humans, animals, or plants to provide an advantage in combat. After the First World War, many nations began to develop biological warfare programmes, but none were as large as Japan's. From 1931 to 1945, unit 731, based in Manchuria, killed more than 20,000 individuals, including prisoners, allied prisoners of war, and civilians during their testing and trials of biological agents (Riedel 2004). After the Second World War ended, the United States, United Kingdom, Soviet Union, and other countries significantly expanded their biological weapons programmes. After years of refinement, it was clear to many nations the devastation these weapons could cause, how indiscriminate they were, and the limited response strategies available if they were used. In 1969, the United States stopped its offensive biological weapons programme, and in 1972 the Biological Weapons Convention Treaty (BWCT) was ratified. As of July 2013, 170 countries have ratified this treaty, which explicitly prohibits the development, stockpiling, and use of biological weapons (United Nations 2013).

While it was suspected that the Soviet Union, a signer of the BWCT, had continued work after an unusual anthrax outbreak in 1979, it was not until 1992 that it was confirmed that *Bacillus anthracis*, which causes anthrax, was accidentally released at a

military facility in Sverdlovsk, infecting at least 77 people and killing 66 (Dembek 2011). After the collapse of the Soviet Union, evidence was found that described the massive nature of its biological weapons programme. It has since been dismantled.

In 1991, the United Nations confirmed that Iraq also had an extensive biological weapons programme, which eventually was dismantled and destroyed. While it is suspected that other nations such as North Korea have biological weapons programmes, this information has not been confirmed. The BWCT does not allow for verification that countries are following the treaty, and the inability to independently verify the dismantling of biological weapons programmes has posed challenges.

While it is possible that a nation could still use a biological weapon, the biggest threat today comes from terrorists using biological agents. Biological terrorism is the intentional release of a biological agent(s) or toxin(s) to incapacitate or kill humans, animals, or plants. While biological terrorism can result in a substantial disease impact, the psychological impact can be profound; this makes biological agents attractive to terrorists. Many organizations have threatened to use biological agents, but to date there has been limited use of them for terrorism purposes. In the autumn of 1984, a Bhagwan Shree Rajneesh sect based in Oregon contaminated multiple salad bars with *Salmonella typhimurium* in an effort to change the outcome of an election by reducing the number of people healthy enough to vote (Torok et al. 1997). In July 1993, the Aum Shinrikyo cult released aerosolized *B. anthracis* from the roof of its building in downtown Tokyo (Takahashi et al. 2004). Several technical failures prevented this release over several days from having human health impacts. In the autumn of 2001, the US government concluded that Dr Bruce Ivins had mailed five letters that contained *B. anthracis* to the media and politicians. These letters resulted in 22 people becoming infected with anthrax and five of them dying (Jernigan et al. 2002; Rasko et al. 2011). This limited attack using the US postal system almost stopped mail delivery across the country, and the decontamination of contaminated facilities cost approximately \$320 million (Schmitt and Zacchia 2012). These events and the continued desire of terrorist groups like Al Qaeda and their affiliates to acquire or develop biological weapons serve as a reminder of the need for preparedness against biological terrorism.

Agents of concern

Numerous infectious diseases harm humans, but only a select number are considered to be agents of concern for biological warfare or terrorism. These agents have characteristics that make them

Table 8.18.1 US government classification of biological agents that could be used as a weapon

Category A	
Definition	Highest priority agents that pose significant risk to public health and national security
Characteristics	<ul style="list-style-type: none"> • Can be easily disseminated or transmitted from person to person • Result in high mortality rates and have the potential for major public health impact • Might cause public panic and social disruption • Require special action for public health preparedness
Examples of diseases (agents)	<ul style="list-style-type: none"> • Anthrax (<i>Bacillus anthracis</i>) • Plague (<i>Yersinia pestis</i>) • Smallpox (variola) • Tularaemia (<i>Francisella tularensis</i>) • Viral haemorrhagic fevers: <ul style="list-style-type: none"> • Filoviruses: <ul style="list-style-type: none"> • Ebola • Marburg • Arenaviruses: <ul style="list-style-type: none"> • Lassa • Machupo • Toxins • Botulism (<i>Clostridium botulinum</i>)
Category B	
Definition	Second-highest priority agents
Characteristics	<ul style="list-style-type: none"> • Are moderately easy to disseminate • Result in moderate morbidity rates and low mortality rates • Require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance
Examples of diseases (agents)	<ul style="list-style-type: none"> • Brucellosis (<i>Brucella</i> species) • Glanders (<i>Burkholderia mallei</i>) • Melioidosis (<i>Burkholderia pseudomallei</i>) • Psittacosis (<i>Chlamydia psittaci</i>) • Q fever (<i>Coxiella burnetii</i>) • Typhus fever (<i>Rickettsia prowazekii</i>) • Food safety threats: <ul style="list-style-type: none"> • <i>Salmonella</i> species • <i>Escherichia coli</i> O157:H7 • <i>Shigella</i> • Water safety threats: <ul style="list-style-type: none"> • <i>Vibrio cholera</i> • <i>Cryptosporidium parvum</i> • Toxins: <ul style="list-style-type: none"> • Epsilon (<i>Clostridium perfringens</i>) • Ricin (<i>Ricinus communis</i> [castor beans]) • Staphylococcal enterotoxin B
Category C	
Definition	Third-highest priority agents including emerging pathogens that could be engineered for mass dissemination in the future
Characteristics	<ul style="list-style-type: none"> • Availability • Ease of production and dissemination • Potential for high morbidity and mortality rates and major health impact
Examples of agents	<ul style="list-style-type: none"> • Nipah virus • Hantavirus

more likely to be used in biological warfare or terrorism. The US Centers for Disease Control and Prevention (CDC) has grouped these characteristics into risk categories A, B, and C (Table 8.18.1). Most preparedness for bioterrorism is focused around category A agents. These agents can be easily disseminated, cause severe disease and high mortality rates if not treated properly, and can pose significant challenges for management and response, which could give rise to public panic.

In 2002, the Public Health Security and Bioterrorism Preparedness and Response Act was passed and signed into law. The US Department of Health and Human Services (DHHS) and the US Department of Agriculture (USDA) were required by this law to identify biological agents or toxins that could have significant human and/or agricultural health impacts. These agents became known as select agents. Those using, possessing, or transferring these agents must follow stringent guidelines, biosafety standards, and protocols (42 CFR Part 73; 9 CFR Part 121; 7 CFR Part 331). The list of select agents is periodically updated, with the last update in October 2012. Several of the select agents are denoted as Tier 1 agents, which require additional security measures to be in place. Tier 1 agents are listed in Box 8.18.1. All category A agents and two category B agents have been identified as Tier 1 select agents.

Dispersal of agents

To be used in biological warfare or terrorism, these agents need to be distributed to their intended targets while remaining infectious. Large-scale distribution would require either of two primary routes: aerosols and products.

The aerosol route requires the agent to be propagated and treated in a manner that allows for small particles (1–5 µm) to be inhaled. Aerosolized agents can be widely distributed either as a slurry using a nozzle that generates an aerosol or as a fine powder. The liquid-based aerosols can be used to attack large areas by using a crop-dusting plane or confined spaces by releasing aerosols into ventilation systems. Fine powders can contaminate large indoor areas and pose risks for re-aerosolization, as noted during the 2001 anthrax letter attacks.

The other possible route of attack is using products that are consumed or used in daily life. Food is the product of most concern. Given the global distribution of the food supply chain, an agent could be introduced anywhere along the chain. While it is likely that treatment steps, such as cooking food or sanitizing water, will kill the agent or reduce its concentration to below infectious levels, infection through this route cannot be ruled out.

While all Tier 1 agents are infectious, only smallpox, plague, and the viral haemorrhagic fevers (Ebola and Marburg) are of concern with regard to subsequent person-to-person transmission. These agents can be responsible for amplified outbreaks due to secondary and tertiary transmission after the initial attack. They also raise the risk of an individual deliberately infecting him- or herself or others as a means of attack—in essence, becoming a biological suicide bomber.

Characteristics of agents

Bacterial

Anthrax

The causative agent of anthrax (Center for Infectious Disease Research and Policy (CIDRAP) 2013a) is the large Gram-positive bacillus *Bacillus anthracis* (American Society for Microbiology (ASM) 2013a). It is a rapidly growing, non-motile, catalase-positive, aerobic/facultative anaerobic organism. Vegetative bacilli are not environmentally stable and readily form spores in the presence of oxygen or when nutrients are exhausted. These spores are extremely environmentally stable and can remain viable for decades.

Anthrax spores are found in soil around the world. Most mammals are susceptible to anthrax, and infections are common in grazing animals. Human infections primarily stem from contact with contaminated animal products. There are four clinical forms of anthrax in humans: cutaneous, inhalation, gastrointestinal, and injection. Cutaneous and inhalation are the two forms most likely to result from a bioterrorism event. During an aerosol event, inhalation and cutaneous anthrax would be common routes of infection initially for those in the plume of anthrax spores. Once they settle out of the air, they can be re-aerosolized, allowing for additional rounds of infections.

Inhalation anthrax

When small particles (1–5 µm) of *B. anthracis* are inhaled, the particles end up in the alveoli of the lungs (ASM 2013a). The minimum infectious dose for inhalation anthrax has been estimated to be between 10 and 8000 spores, with an uncertain dose–response association (Franz et al. 1997; Fennelly et al. 2004; Coleman et al. 2008). In the lungs, macrophages ingest the spores, transporting them to the lymph nodes (Russell et al. 2008). At this point the spores germinate and multiply, enabling a systemic infection to occur. During the initial stage of infection, symptoms include fever, fatigue, cough, chills, and malaise (Jernigan et al. 2001). These non-specific symptoms make it hard to initially diagnose anthrax without laboratory testing. If this initial phase of infection is not treated, the infection enters the final phase, with a rapidly progressing fever signalling the onset of respiratory and cardiac collapse. Without prompt treatment, the case-fatality rate for inhalation anthrax approaches 80 per cent (Holty et al. 2005), but early, aggressive treatment can cut that rate in half. Inhalation

anthrax is treated with ciprofloxacin or doxycycline plus two additional antibiotics (Malecki et al. 2001). Post-exposure prophylaxis involves ciprofloxacin, doxycycline, or levofloxacin. An anthrax vaccine is available under emergency use authorization for use in adults in combination with antibiotics after a widespread airborne release of anthrax (Wright et al. 2010). The incubation period for inhalation anthrax ranges from 1 to 6 days.

Cutaneous anthrax

Abrasions or cuts on the skin provide an opportunity for anthrax spores to germinate at the site, creating a papule. As spores begin to multiply, the vegetative cells end up in the regional lymph nodes. This results in painful oedema and ulcerations around the original papule. After a few days a black eschar forms over the ulcerated papule. In most people these infections resolve without complications with proper antibiotic treatment (Inglesby et al. 2002). Cutaneous anthrax is treated with ciprofloxacin or doxycycline.

Plague

The causative agent of plague is a Gram-negative bacillus, *Yersinia pestis* (CIDRAP 2013b). It is a slow-growing, non-motile, catalase-positive, facultative anaerobic organism (ASM 2013b). *Y. pestis* is not considered environmentally stable and will die within a few hours. Wild rodents are the primary reservoir for *Y. pestis*, although many mammals can become incidental hosts (Perry and Fetherston 1997). The flea is the vector sustaining transmission of plague. Plague is endemic in many regions of the world, particularly Africa, Asia, and the Americas. Most human cases are the result of contact with infected mammals or fleas.

There are three primary forms of plague: bubonic, pneumonic, and septicemic (Perry and Fetherston 1997; Inglesby et al. 2000). Without proper treatment, bubonic and pneumonic plague generally turn into septicemic plague and are fatal. Pneumonic plague is the form most likely to result from a bioterrorism event. Pneumonic plague can be spread person to person through respiratory droplets, but most naturally occurring cases do not result in secondary transmission, although it is possible that super-spreading events can occur (Hinckley et al. 2011).

During an aerosol event, *Y. pestis* would be inhaled; as few as 100 organisms can cause an infection. The incubation period is typically 1–4 days but is dose-dependent, with symptoms possible in less than 24 hours after a significant exposure. Initial symptoms include nausea, vomiting, diarrhoea, and abdominal pain, without evidence of a respiratory infection. A fever, productive coughs (with evidence of blood), chest pain, and cyanosis typically follow (Inglesby et al. 2000). A key indicator of pneumonic plague is the rapid development of severe pneumonia symptoms after gastrointestinal symptoms (Babin 2010). Disease progression is rapid, septicemia is common, and prompt treatment is critical. Without proper treatment within 24 hours of symptom onset, the case-fatality rate approaches 100 per cent, with death typically occurring within 5 days (Gage et al. 2000; Inglesby et al. 2000). Streptomycin or gentamicin are the primary treatment options for pneumonic plague (Inglesby et al. 2000), while doxycycline or ciprofloxacin are the primary antibiotics for post-exposure prophylaxis. A vaccine for plague is not currently available (Food and Drug Administration 2014).

Tularaemia

The causative agent of tularaemia (CIDRAP 2013c) is the small Gram-negative coccobacillus *Francisella tularensis* (ASM 2013c).

It is a slow growing, non-motile, weakly catalase-positive aerobic organism. *F. tularensis* can survive for prolonged periods in moist environments, such as brackish water (Berrada and Telford 2011). Environmental amoebae can also ingest *F. tularensis*, thereby increasing its survival in the environment. Small mammals are the primary reservoirs for *F. tularensis*. Ticks, mosquitoes, and biting flies are all known vectors. There are four subspecies of *F. tularensis*: *tularensis* (type A), *holarctica* (type B), *mediasiatica*, and *novicida* (Sandström et al. 1992; Farlow et al. 2005; Huber et al. 2010). All four subspecies can cause human disease, with subspecies *tularensis* (type A) causing the most severe disease. Type A is found primarily in the United States and contains two distinct clades: 1 and 2. Type B is found around the world and is the primary source of *F. tularensis* infections outside the United States.

Tularaemia symptoms range from acute-onset pneumonia to painful lesions that can take weeks to resolve. Ulceroglandular, glandular, and pneumonic tularaemias are the most common clinical syndromes (Dennis et al. 2001). Pneumonic tularaemia is the most likely form to result from a bioterrorism event in which the agent is released into the air. Tularaemia is not contagious.

During an aerosol event, *F. tularensis* could be inhaled, and as few as ten organisms can cause an infection (Franz et al. 1997). The incubation period is typically 3–5 days. Initial symptoms include nausea, a non-productive cough, sudden onset of fever, and myalgia, with pneumonia that doesn't respond to typical treatment (Dennis et al. 2001). Without proper antibiotic treatment, the case-fatality rate approaches 80 per cent but drops to less than 10 per cent with proper treatment. Streptomycin or gentamicin is the primary treatment choice for pneumonic tularaemia, while doxycycline or ciprofloxacin is the primary option for postexposure prophylaxis (Dennis et al. 2001). No vaccine for tularaemia is currently licensed for use.

Glanders

The causative agent of glanders (CIDRAP 2012a) is a Gram-negative coccobacillus, *Burkholderia mallei*. It is a slow-growing, non-motile, catalase-positive, aerobic/facultative anaerobic organism (ASM 2013d). It is an obligate mammalian pathogen without an environmental reservoir. In most environments it is quickly inactivated, but it can remain viable in warm and moist environments for 2–3 weeks.

The primary mammalian reservoir for *B. mallei* are equids (Dvorak and Spickler 2008). Glanders is a rare human disease, with most human infections occurring from exposure to infected horses or laboratory exposures. There are three primary routes of exposure: inoculation, ingestion, and inhalation (Gilad et al. 2007; Dembek 2011). It is assumed that the infectious dose for *B. mallei* is low. The clinical course of glanders is varied and characterized by four types of infection: localized, pulmonary, septicemic, and chronic. Pulmonary infections are the likeliest to stem from bioterrorism, as they result from an airborne release of *B. mallei*. Without proper treatment, pulmonary infections typically result in septicemic glanders as early as a week after symptom onset and may become chronic. Treatment of glanders consists of two phases: intensive therapy with ceftazidime or meropenem, then eradication with TMP/SMX or amoxicillin/clavulanic acid (Lipsitz et al. 2012). Because of the risk of relapse, treatment typically lasts 14 weeks, and follow-up can last for years (Dembek

2011). There is no vaccine for glanders. Without proper treatment, the septicaemic form of glanders is normally fatal, but with proper treatment the case-fatality rate drops to 50 per cent. The incubation period for the pulmonary form is from 1 to 14 days. Although there have been rare cases of human-to-human transmission of glanders, it is generally not considered contagious.

Melioidosis

The causative agent of melioidosis (CIDRAP 2012a), *Burkholderia pseudomallei*, is a Gram-negative, slow-growing, motile, catalase-positive, aerobic/facultative anaerobic bacillus (ASM 2013d). *B. pseudomallei* is a saprophyte and remains viable in the soil and water, its reservoir, for years. It is endemic in South East Asia and northern Australia. Human infections are most common after significant rainfall and primarily affect soldiers, agriculture workers, or those with compromised immune systems who have exposure to contaminated soil or water (Baker et al. 2011; Dembek 2011; Vidyakshmi et al. 2012).

Melioidosis can have a wide variety of clinical presentations, making diagnosis challenging, especially when cases occur outside of endemic regions. Clinical presentations can be grouped into four types: localized, pulmonary, septicaemic, and disseminated (Dembek 2011). Again, pulmonary infections are the greatest concern for bioterrorism, as they result from an airborne release of *B. pseudomallei*. These infections can be mild to severe, with pulmonary abscesses and productive cough. Pulmonary infections may lead to septicaemic infections, which are often fatal without proper treatment and fatal half the time with proper treatment. Treatment of melioidosis is identical to glanders (Lipsitz et al. 2012) and lasts as long (Dembek 2011). *B. pseudomallei* is naturally resistant to aminoglycosides and macrolides. There is no vaccine for melioidosis. The incubation period for *B. pseudomallei* is wide-ranging; cases can involve clinical symptoms within days of exposure or years after exposure. Although there have been rare cases of human-to-human transmission of melioidosis, it is generally not considered contagious.

Viral

Smallpox

The causative agent of smallpox (CIDRAP 2013d) is brick-shaped DNA virion, variola virus (ASM 2013e). It is assumed that environmental survival for variola would be similar to the vaccinia virus, which is quickly destroyed in high temperature and humidity (Henderson et al. 1999). Variola is stable in smallpox scabs for up to 4 months (MacCallum and McDonald 1957). Humans are the only host for smallpox; there are no animal or environmental reservoirs. Smallpox was officially declared eradicated in December 1979; therefore, any case would likely be associated with a laboratory accident (stocks of the virus are officially stored in high-security labs in the United States and Russia) or terrorism (Fenner et al. 1988; Henderson et al. 1999). Most of the world's population is susceptible to smallpox now, as vaccination has not routinely occurred for decades.

The variola virus has been classified as variola major or minor, primarily based on severity of symptoms. Variola minor typically produces a less severe infection. There are five clinical types of smallpox, with over 90 per cent of cases being ordinary (classic) smallpox (Fenner et al. 1988). The incubation period for ordinary smallpox is typically 12 days but can range from 7 to 19 days. The initial stage of infection consists of fever, headache, backache,

chills, and vomiting. Around day 5 a rash begins near the mouth (Fenner et al. 1988; Henderson 1999). The rash spreads from the face to the trunk and then the extremities. The lesions are maculopapular for the first 2 days, then vesicular for the next 3 days, then pustular for a week. Eventually these pustular lesions scab over and fall off. The pustules are hard and slightly raised and appear as confluent, semiconfluent, or discrete.

Smallpox is primarily transmitted by respiratory droplets or aerosols (Fenner et al. 1988; Milton 2012). The infectious dose is fewer than 100 virions, and the disease is highly contagious (Franz et al. 1997). Individuals are most contagious during the first week after rash onset and typically infect three to six other people. Treatment for smallpox typically consists of supportive care. A vaccine is available in large quantities and is the primary means of controlling an outbreak. If the vaccine is provided within 4 days of exposure, it significantly reduces morbidity and mortality (Dixon 1948; Henderson et al. 1999). The overall case-fatality rate for ordinary smallpox is 30 per cent in an unvaccinated population (Rao 1972). Other forms of smallpox, like the flat-type and haemorrhagic, have case-fatality rates of over 90 per cent. These rates, however, may be significantly different with modern medicine, which includes investigational antiviral drugs against the variola virus and critical care medicine.

Viral haemorrhagic fevers

The diseases caused by several RNA viruses from, for example, the families Arenaviridae (Lassa), Bunyaviridae (hantavirus), Filoviridae (Ebola), and Flaviviridae (dengue) are known as viral haemorrhagic fevers (Marty et al. 2006; King et al. 2011; CIDRAP 2012b). These viruses are all capable of causing haemorrhagic symptoms to varying degrees. The Ebola and Marburg viruses will be reviewed in more detail, as they are listed as Tier 1 agents (Animal and Plant Health Inspection Service 2014).

Four of the five Ebola subtypes are found in sub-Saharan Africa, including Zaire, Sudan, Côte d'Ivoire, and Bundibugyo (Leroy et al. 2011). The fifth subtype, Reston, is found in the Philippines and so far has not been associated with human disease (Miranda et al. 1999). The case-fatality rates for the four strains of Ebola in Africa are varied and can reach 90 per cent for the Zaire subtype (Feldmann and Geisbert 2011). Ebola is assumed to be primarily transmitted by body fluids of infected humans or animals. It can theoretically be transmitted by aerosol, which is of concern for bioterrorism (Borio et al. 2002). The incubation period ranges from 2 to 21 days. Symptoms include fever, headache, myalgia, maculopapular rash, prostration, diarrhoea, vomiting, and jaundice (Feldmann and Geisbert 2011; Kortepeter et al. 2011). Evidence of haemorrhages may occur toward the end of the disease progression.

Marburg is also found in sub-Saharan Africa. It is very similar clinically to Ebola but typically not as deadly. Supportive care is the only treatment available for Ebola and Marburg (Borio et al. 2002; Feldmann and Geisbert 2011). No antivirals have been shown to be effective for either disease, and a vaccine is not available. Outbreaks are controlled by strict contact precautions and contact tracing.

Toxins

Botulism

The causative agent of botulism (CIDRAP 2012c) is a toxin produced by *Clostridium botulinum*. It is a Gram-positive, anaerobic,

spore-forming, motile bacillus (ASM 2013f). It is commonly found in soil. Spores are extremely environmentally stable, and their germination produces botulinum toxin. Eight different botulism toxins have been identified: A through H (Franz et al. 1997; Barash and Arnon 2014), with type A, B, and E toxins the most common causes of human disease (CDC 1998; Shapiro et al. 1998). The botulism toxin is the most lethal toxin known and can be ingested, inhaled, or injected (Franz et al. 1997). The ingestion and inhalation routes are the most concerning from a bioterrorism standpoint. The incubation time for ingestion of the toxin can be as short as 2 hours and up to 8 days (Arnon et al. 2001). The incubation time for inhalation botulism is unknown. Botulism is characterized by an acute, afebrile, descending flaccid paralysis (Shapiro et al. 1998; Arnon et al. 2001). Supportive care and treatment with the botulinum antitoxin are the primary response strategies. The case-fatality rate for ingestion botulism is under 10 per cent, while the case-fatality rate for inhalation botulism is unknown. Treatment of botulism typically requires intensive care, such as mechanical ventilation, which likely would be in short supply during an attack, thus increasing the case-fatality rate.

Public health surveillance and preparedness for bioterrorism

Surveillance

A robust public health surveillance system is the primary vehicle through which an unusual emerging infectious disease or bioterrorism event will be detected. These surveillance systems comprise three main components: laboratory (including routine reportable disease surveillance), syndromic, and environmental surveillance (Kman and Bachmann 2012). Laboratories around the world that process clinical samples are typically required to alert public health authorities if they detect an agent of concern for bioterrorism. Regulations regarding the agents to be reported and the time frame for reporting vary by jurisdiction. Laboratory-based surveillance takes time and can require several hours to days after a sample is collected before results are available, but it provides evidence of a specific organism, which is key for initiating the appropriate public health response.

Syndromic surveillance involves the collection of data from cases with defined and common symptoms within a defined population. The number of physicians reporting patients with influenza-like illness (ILI) every winter is a common form of syndromic surveillance. With the appropriate background information about symptoms in a defined population, a baseline syndromic surveillance measurement can be useful for identifying unusual increases in patients with similar symptoms. For example, if hospitals started reporting an increase in patients presenting with ILI in June that was above the June baseline, this finding would be cause for concern. An investigation should be initiated to determine the cause of the sudden increase in ILI. The CDC has a national programme called BioSense that is based on the timely review of aggregated syndromic surveillance data. Many countries and some large cities have similar programmes. There are also several Internet-based tools useful for syndromic surveillance and analysis (Salathe et al. 2013). Syndromic surveillance can be critical for identifying unusual events that could be the result of a covert biological attack.

Environmental surveillance consists of environmental monitoring for biological agents. The US military and other militaries have developed environmental monitoring systems that can alert them to biological, chemical, or radiological attack from a distance. Civilian detection capabilities typically rely on environmental monitoring in fixed locations. The BioWatch programme currently in use in the United States is a fixed-location environmental monitoring system for select biological agents (Kman and Bachmann 2012). These systems can provide an early warning that a biological agent was present at the location having a positive detection. This allows for public health and law enforcement authorities to conduct an investigation of the cause of the positive result, in theory before any individuals become sick. If it is determined that a bioterrorism attack has occurred, the appropriate public health response can be initiated before syndromic surveillance is able to detect unusual illness patterns. This finding can potentially prevent significant morbidity and mortality if immediate public health action occurs, including the widespread distribution of appropriate antibiotics and vaccines.

Preparedness for bioterrorism

Even a limited bioterrorism event will likely overwhelm public health and medical authorities. The anthrax mailings in 2001, for example, strained national, state, and local public health response capabilities. While there have been major advances in preparedness since 2001, the current climate of fiscal austerity has stalled or started to reverse most of these gains (Gursky and Bice 2012). The location or region responding to the bioterrorism event will likely need to alter its standards of care owing to the number of patients, limited staff availability (due to illness, exhaustion, or other reasons), and shortages of supplies necessary for treating patients as well as individuals needing routine or emergency medical care.

The public health and medical communities have done extensive work on altering the standards of care to meet surges in medical care needs during disasters, and handbooks are available on how to manage these large-scale events (Barbera and Macintyre 2007, 2009). The US Institute of Medicine has extensively reviewed the guidelines for establishing crisis standards of care, frameworks for responding to these disasters, and triggers for implementing these standards (Altevogt et al. 2009; Hanfling et al. 2012; Hanfling et al. 2013). These guidelines help ensure that the care meets legal, ethical, and medical standards during a crisis. Basic medical care, such as supportive care and rapid access to the right medical countermeasures, is paramount during a crisis, as it will help the greatest number of people.

In the United States, staffing support during a large-scale response such as a bioterrorism attack would come from a variety of federal and volunteer sources. At the federal level there are rapidly deployable teams of medical and public health professionals within the DHHS that could respond, such as the Disaster Medical Assistance Teams (DMATs) (Frasca 2010). The Department of Defense has similar support capacity that could be used under certain conditions. A cadre of volunteers from the Red Cross and other disaster relief agencies and the Medical Reserve Corps are also available (Frasca 2010).

The quantity of medical countermeasures necessary for treating a large population is unlikely to be present in the location of a bioterrorism event. Some national governments maintain strategic national stockpiles (SNS) with medical countermeasures available

for rapid deployment. In the United States, the CDC maintains the SNS and there are plans in each state and many cities for how to rapidly distribute its resources to the public and first responders in the event of a bioterrorism attack. The SNS contain enough treatment or prophylactic doses of antibiotics, vaccines, and other medical products such as personal protective equipment and ventilators to support a response in several US cities simultaneously.

The development of medical countermeasures to respond to bioterrorism has been a challenge. To date the greatest success in medical countermeasure enhancement has been against smallpox, with a new vaccine and new treatment options available and stockpiled. Medical countermeasure development globally has been supported primarily by the US government, specifically through the Biomedical Advanced Research and Development Authority. While work has been done on developing vaccines and other medical countermeasures, primarily antibiotics, the work has met with limited success; several regulatory, procedural, and financial challenges must be overcome (Russell and Gronvall 2012).

Challenges for the future

Dual-use research of concern

Scientific advances have enabled countless benefits to society; however, the tools used to arrive at these benefits may also cause harm. Some dual-use research raises significant potential for misuse, known as dual-use research of concern (DURC). A virus engineered to be more transmittable in an effort to understand the risk it possesses to public health would be considered as DURC, for example. The work can be done by a scientist with altruistic motivations or it could be done by a terrorist. If there were a laboratory accident that released the new agent from the lab or if it were intentionally released, the public health impact could be the same. In 2004, the National Research Council identified seven types of experiments that raised concern regarding their potential for misuse (Committee on Research Standards and Practices to Prevent the Destructive Application of Biotechnology 2004). These types of experiments are supposed to be reviewed for additional biosecurity information at the institution conducting the research, and oversight is primarily a local issue (Epstein 2012). The National Institutes of Health has created requirements for Institutional Biosafety Committees, which would be the groups responsible for reviewing these experiments at the institutional level.

The National Science Advisory Board for Biosecurity (NSABB) was created as an advisory body to the US Government on dual-use and DURC issues. NSABB has, among its guidance documents, proposed a strategy for minimizing misuse of research information, a code of conduct for responsible research, and guidance for educating amateur biologists on dual-use issues (NSABB on Biosecurity 2007, 2011, 2012). These guidelines only apply for US Government-funded research. The World Health Organization published guidelines for responsible life science research in 2010 (World Health Organization 2010). The publication and dissemination of research with DURC potential is a controversial issue, largely left to the decision of journal editors who don't necessarily have clear guidelines or experience with this topic (Patrone et al. 2012). This became very clear recently with the controversy surrounding and subsequent publication of two studies on highly pathogenic influenza A/H5N1 virus in which the viruses were

modified to be more transmittable among mammals (Osterholm et al. 2012).

Conclusion

History shows us that individuals have tried and will continue to try to use biological agents for terror. A large-scale bioterrorism event would be unprecedented, straining and challenging every facet of medical and public health response. In our globally connected economy with its just-in-time supply chains, any large-scale bioterrorism event would quickly become a global event because of both the potential risk of infection and the shock to the global economy. A robust public health and medical workforce is necessary to respond effectively and efficiently to these types of events.

Introduction to tobacco use

Please respond to the following statements before reading further:

1. About one out of 20 smokers (i.e. 5 per cent or less), if they continue to smoke, will eventually be killed by smoking.
2. To reduce deaths caused by smoking, preventing young people from smoking is the most important action.

Response: strongly agree/agree/disagree/strongly disagree.

Most people will choose agree or strongly agree for these two statements. However, in fact, smoking kills one in two smokers and quitting smoking prevents more deaths more quickly.

Tobacco is the world's most important and most avoidable public health problem. Tobacco killed 100 million people in the last century, mostly in developed countries, and could kill 1 billion this century, mostly in low- and middle-income countries (LMICs) especially China. Currently, tobacco kills 5.4 million people every year. Unless urgent action is taken, tobacco will kill 8 million per year by 2030, 80 per cent of whom will be in developing countries. 'Of the more than 1 billion smokers alive today, around 500 million will be killed by tobacco' (World Health Organization (WHO) 2008). But millions of lives have been saved since the 1960s, mostly in developed countries (notably the United States and United Kingdom) which have progressively and successfully implemented effective tobacco control policies.

Tobacco control is the most remarkable example of global public health actions against non-communicable diseases (NCDs). It is unique in having an international public health treaty, the WHO Framework Convention on Tobacco Control (FCTC), which has been ratified by 176 parties covering 88 per cent of the world's population (as of 30 November 2012). It is one of the most rapidly ratified United Nations (UN) treaties of all time but two of the world's largest countries have not ratified the FCTC, namely the United States and Indonesia (WHO 2012a).

In the September 2011 Political Declaration of the UN on NCDs, tobacco use tops the list of four major risk factors that also include the harmful use of alcohol, unhealthy diet, and physical inactivity (UN 2011).

Globally, the epidemic of tobacco-induced diseases, mortality, and related social and economic burden is still expanding. Using the host-agent-vector model of infectious diseases, the tobacco epidemic is an epidemic of the agent, that is, tobacco. It is sometimes also described as an epidemic of smoking and its harms to others. These two descriptions tend to blame the agent (tobacco) and the host (smokers) or focus on the victims (passive smokers).

However, some might also consider that the tobacco epidemic is really a tobacco industry epidemic. The agent is produced massively, its use by the host is heavily promoted, and control measures are aggressively obstructed by the vector, the tobacco industry. There will be no tobacco epidemic without the tobacco industry. Tobacco control must therefore target the vector. Helping the hosts, that is, smokers, to quit smoking and preventing non-smokers, especially young people and women, from starting smoking are also important, but the impact will be limited to those who can be and are being helped effectively. Smoking cessation campaigns and services cannot produce substantial public health benefits when the tobacco industry is not under strict control. The success of tobacco industry control and other control measures will lead to more quitting, less relapse, and less uptake of smoking.

Effective control measures are stated in the FCTC and translated into six policies of WHO's MPOWER package as follows (WHO 2008):

- ◆ *Monitor* tobacco use and prevention policies.
- ◆ *Protect* people from tobacco smoke.
- ◆ *Offer* help to quit tobacco use.
- ◆ *Warn* about the dangers of tobacco use.
- ◆ *Enforce* comprehensive restrictions on tobacco advertising, promotion, and sponsorship.
- ◆ *Raise* taxes on tobacco.

Note that these six policies are not ranked, and all six are needed as a comprehensive approach against the tobacco industry and tobacco use. However, their implementation varies greatly even among countries that have ratified and are parties of the FCTC. WHO evaluates the progress and publishes global status reports regularly, which is part of the M ('monitor') under MPOWER.

Tobacco kills up to two in three smokers

At least one in two smokers killed

It is important to understand and warn about the dangers of tobacco use: first, the absolute risk of death from all causes combined, and second, the large number of resultant deaths globally, regionally, and locally. This absolute risk, that a smoker will have a 50 per cent chance of being killed by tobacco, is easy to understand and more relevant to individuals than relative risks (RRs) or number of deaths. RRs only tell the exposed people that they

Fig. 9.1.1 One in two smokers will be killed by smoking.

have higher risks than those who are unexposed, but not the exact probability of harm, the absolute risk. Large RRs do not mean large absolute risks if the incidence rate in the unexposed is low. Telling smokers that millions have died from tobacco elsewhere might be alarming to some, but difficult to comprehend to others.

The WHO statement ‘Tobacco kills up to one in every two users’ (WHO 2008) is derived from Peto, who stated ‘about half of teenagers who keep smoking steadily will eventually be killed by tobacco (about a quarter in old age plus a quarter in middle age)’ (Peto 1994) (see Fig. 9.1.1). This was based on the translation of the RR of two in the prospective British Doctors Study by Doll and Peto with 40 years of follow-up (Doll et al. 1994). This is a unique example of how an RR can be translated into absolute risk for public health actions and communication of risks.

From relative risk to absolute risk

The RR is the absolute risk of disease or mortality in the exposed group (smokers) divided by that in the unexposed (non-smokers). Translating the RR into an absolute risk in the exposed without knowing the absolute risk in the unexposed is only feasible for total or all-cause mortality. This is based on the attributable fraction (AF) in the exposed ($AF = (RR - 1)/RR$). With an RR of two for total mortality in smokers compared with non-smokers, the AF in smokers is $(2 - 1)/2 = 0.5$. That means of all smokers who died, half were due to smoking. Because all smokers will eventually die, the denominator of all smoker deaths can be turned into all current smokers who are alive, and hence of all current smokers, 50 per cent or one in two will eventually be killed by smoking (Lam 2012).

Up to two in three smokers killed

Previously reported RRs could have been underestimated. The RR is based on a comparison of mortality rates of current smokers and non-smokers after some years of follow-up. Current smokers recruited at baseline are survivors as their weaker counterparts might have died. Non-smokers can be either never smokers or former smokers. The latter could have quit smoking while still being healthy (healthy quitters), or they had to quit because of ill health

(ill quitters). Hence, RR can be underestimated as current smokers tend to be healthier (lower mortality rate in the numerator), and non-smokers can include some ill quitters (greater mortality rate in the denominator). This bias is particularly strong when a cohort includes older people.

Another bias could be due to insufficient duration of follow-up, especially for diseases that take many years to develop. A longer follow-up would yield more deaths and allow subgroup analysis. The results from Doll and Peto’s study, after 50 years of follow-up, showed that if smoking started at a young age, two in three smokers (RR of 3) will be killed by smoking (Doll et al. 2004). That two in three very young smokers will be killed by smoking is particularly relevant for controlling smoking in children and youth, but this statement has not yet been publicized widely. Latest findings based on large contemporary cohorts in the United States and United Kingdom also revealed all-cause mortality RRs approaching 3 in male and female current smokers compared with never smokers (Jha et al. 2013; Pirie et al. 2013; Thun et al. 2013).

Not many cohort studies, especially those from LMICs, have been followed up for as long as the British doctor cohort studies and hence, their RRs of mortality due to smoking tend to be underestimated. In a small cohort of 1696 people followed up for 20 years, Lam et al. (1997) found an RR of about 2, which is similar to that from Doll and Peto but greater than those of earlier (Yuan et al. 1996) and more recent cohort studies from China (Elliott et al. 2009) with shorter duration of follow-up.

The total exposure to tobacco in smokers varies by countries and cohort studies. Another explanation for the smaller RRs of cohort studies in China and other LMICs at an earlier stage of the tobacco epidemic is that their exposure to tobacco could be lower. Smokers in these cohort studies tended to have started smoking at an older age and could not afford to smoke as much as those in high-income countries.

A recent meta-analysis by Gellert et al. (2012) on smoking and all-cause mortality focused on elderly people (aged 60 or above). Based on 17 cohort studies from seven countries, the RR was 1.85 in current smokers. This means that the one in two deaths is still applicable to older smokers.

Public health applications

Such epidemiological findings can be used for more effective public health advocacy, education, and publicity campaigns. The AF of 50 per cent can be translated into the number of people in a specific population who will be killed by smoking. If there are 4 million adults, and the prevalence of smoking is 50 per cent, the number of people to be killed is $4 \text{ million} \times 0.5 \times 0.5 = 1 \text{ million}$. The same can be applied to children and young people. A statement that among today's 4 million children in our country/city/district, about 1 million will be killed by tobacco, if the current prevalence of smoking is not reduced, is more striking. On the other hand, such figures can be used positively, saying that prevention of smoking and promotion of quitting can save millions of lives. As there is a trend of increased smoking in children and youth in many LMICs, if the RR of 3 is used, the estimates will be even more alarming.

For unknown reasons, the 'one in two deaths' message is not used in many websites that help smokers quit, including the US Centers for Disease Control and Prevention (CDC) website. The US Surgeon General's (USSG's) report (US Department of Health and Human Services (2004) does not include total mortality. Existing pictorial warnings in cigarette packs of more than 50 jurisdictions also do not show or highlight this risk. Even recent warnings in Canada and Australia in plain packaging do not have it (Physicians for a Smoke-Free Canada n.d.). The 'one in two risk' has seldom been used as a key campaign message until recently. In 2011, Ireland was the first country to use it for a major social marketing campaign resulting in wide media coverage and great increases in calls to the quitline and demand for smoking cessation services (Howell and HSE Social Marketing Working Group on Tobacco 2012). The Hong Kong Council on Smoking and Health launched a campaign on 'one in two' with a video for TV in October 2012. For public health information and education, the mortality risk of 'one in two' to 'two in three' should be highlighted consistently and widely (Lam 2012). For randomized controlled trials on smoking cessation advice or counselling, there is also no report about using such absolute risk warning, and new trials are warranted.

Clinical applications

The AF of 50 per cent can also be used to motivate clinicians or other healthcare professionals (HCPs) to be more active in helping smokers to quit. If they can help two smokers to quit, they would have saved one life. However, the AF does not tell when the smokers will be killed by smoking. The message to the smokers can be simple: 'If you and your good friend continue to smoke, one of you will be killed by smoking prematurely. We cannot predict who and when, but the premature death can come quickly and suddenly, and when it comes, it will be too late. Quit smoking now.'

Note that AF in the exposed can be used in clinical epidemiology for individuals with a disease and is exposed to the risk (causal) factor of the disease. If the RR of lung cancer due to smoking is 20 (Aubin et al. 2011), AF in the exposed is $(20 - 1)/20 = 95$ per cent. Clinically, one can tell the smoker who has lung cancer that the probability that his lung cancer is due to his smoking is about 95 per cent. This probability will be greater if the smoker has smoked heavily for a long duration, as the RR refers to an 'average'

smoker, and there is a dose-response relation between RR and the amount of exposure (i.e. pack-years).

Specific harms of tobacco: active smoking

Causation versus association

Of the four major risk factors, tobacco use is the one confirmed to be a causal factor of the largest number of diseases. Hence, the term 'cause' or 'causal factor' should be used for smoking instead of risk factor, which implies association rather than causation. Similarly, the terms 'tobacco-induced diseases' or 'tobacco-caused diseases' are clearer than terms such as 'tobacco-related' or 'smoking-related' diseases. The USSG reports are the longest and most comprehensive series of reviews, with the latest on active smoking published in 2004 (US Department of Health and Human Services 2004). Updated reports are published regularly often with new harms added to the previous lists. Globally, different review panels use quite similar criteria for causal inference. Despite the remarkable consensus on many diseases, disagreements remain as to whether the evidence is sufficient (or only suggestive) to reach a conclusion on causation for some diseases. More evidence to prove or confirm causation of additional diseases is of scientific interest and can add to the total disease burden estimates, but is not essential for tobacco control.

International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC), a WHO agency, is the world authority in the evaluation of carcinogenic risks to humans. The 1986 and 2002 IARC monographs classify tobacco smoking and tobacco smoke as a Group 1 carcinogen, meaning that there is sufficient evidence that it can cause cancer in human. The most updated and comprehensive reviews released by IARC in 2009 conclude that tobacco smoking is the single largest cause of cancer worldwide, and 'Tobacco smoking causes cancers of the lung, oral cavity, naso-, oro- and hypopharynx, nasal cavity and accessory sinuses, larynx, oesophagus, stomach, pancreas, colorectum, liver, kidney (body and pelvis), ureter, urinary bladder, uterine cervix and ovary (mucinous), and myeloid leukaemia. Also, a positive association has been observed between tobacco smoking and cancer of the female breast. For cancers of the endometrium (post-menopausal) and of the thyroid, there is evidence suggesting lack of carcinogenicity' (IARC 2012). Note that two important cancers are added, that is, cancer of the colon and ovary, for which the evidence is now considered sufficient, but that for breast cancer is still limited (Secretan et al. 2009; IARC 2012). The report also concludes that bidi (hand-rolled cigarette commonly used in South Asia) smoking increases the risk for cancers of the oral cavity, oropharynx, hypopharynx, larynx, lung, oesophagus, and stomach, and smokeless tobacco causes cancer of the oral cavity, oesophagus, and pancreas.

The 2010 USSG report

The 2010 USSG report focused on mechanisms rather than causal inference. The major conclusions are: (1) no risk-free exposure level; (2) tobacco smoke causes adverse health outcomes through DNA damage, inflammation, and oxidative stress; (3) risk is related to the duration and level of exposure; (4) exposures are due to powerful nicotine addiction in the brain; (5) low levels of exposure, including second-hand smoking, lead to rapid and sharp

increases in endothelial dysfunction and inflammation, which are implicated in acute cardiovascular events and thrombosis; and (6) evidence is insufficient that modifications in tobacco production can reduce risks. Moreover, it has important new conclusions that cigarette smoking produces insulin resistance and chronic inflammation, which can accelerate macro- and micro-vascular complications. Hence, for diabetes: (1) smoking increases the risk of type 2 diabetes; (2) people with diabetes need more insulin; and (3) smokers with diabetes have more complications including heart and kidney disease, amputation, retinopathy, and peripheral neuropathy. The report has a very readable booklet for the public that is highly recommended (Centers for Disease Control and Prevention 2010).

Discrepancies and potential confusions

The conclusions on causal relations for cancers from the IARC are mostly similar to the 2004 USSG report. The most notable exceptions are that the 2002 IARC publication has included liver, nasal cavities and nasal sinuses, and nasopharyngeal cancer as causally related to smoking and cancers of the *tongue and lip* are specifically stated under oral cavity. The 2004 USSG report, which appeared later, does not. The 2012 IARC report has now added that smoking causes colon and ovarian cancer. Another notable discrepancy is that although the statement that smoking can cause erectile dysfunction (ED) is often shown in pictorial or other health warnings on cigarette packs, the 2004 USSG report considers that the evidence for causation is only suggestive but not sufficient.

Important new results

Since the 2004 USSG report, there has been no new meta-analysis or systematic review on ED. New results based on cross-sectional surveys have shown a consistent association between smoking and ED in Australia (Millett et al. 2006), Boston (Kupelian et al. 2007), Hong Kong (Lam et al. 2006), and China (He et al. 2007), and a Swiss survey showed that smoking was associated directly with premature ejaculation and indirectly with ED in young men (Mialon et al. 2012). Results from a randomized controlled trial showed that quitting smoking improved ED (Chan et al. 2010). A smoking cessation clinic study showed that quitters had better erectile function than those who relapsed (Harte and Meston 2012). All three meta-analyses in 2007 concluded that smoking is associated with an increased risk of active tuberculosis (TB) disease and mortality (mostly due to reactivation of previous TB infection) and the evidence is strong and consistent (Bates et al. 2007; Lin et al. 2007; Slama et al. 2007). A mathematical model predicted that 'smoking would produce an excess of 18 million tuberculosis cases and 40 million deaths from tuberculosis between 2010 and 2050, if smoking trends continued along current trajectories. The effect of smoking was anticipated to increase the number of tuberculosis cases by 7 percent (274 million v 256 million) and deaths by 66 percent (101 million v 61 million), compared with model predictions that did not account for smoking' (Basu et al. 2011). The causal relation also suggests that tobacco control must be integrated with TB control in TB endemic countries. Public health advocacy has to be based on precise and sometimes conservative estimates of disease burden. With new results, systematic reviews by different authorities will come up with revised or updated conclusions. Public health professionals

need to keep updated and critically appraise the original sources of information.

Specific harms of tobacco: passive smoking

Numerous reviews

No other substance like second-hand smoke (SHS) has been subject to so many systematic reviews within such a short period since the first two reports of an association with lung cancer were published in 1981 (Hirayama 1981; Trichopoulos et al. 1981). The massive and aggressive criticisms from the tobacco industry and its scientists were also unprecedented.

The 2006 USSG report

The 2006 USSG report is the most comprehensive review focusing on SHS (US Department of Health and Human Services 2006). It concludes that the evidence is sufficient that SHS causes: (1) premature death and disease in children and adults who do not smoke; (2) sudden infant death syndrome, acute respiratory infections, ear problems and more severe asthma in children, and smoking by parents causes respiratory symptoms and slows lung growth in their children; and (3) immediate adverse effects on the cardiovascular system, coronary heart disease (CHD) (25–30 per cent increased risk) and lung cancer (20–30 per cent increased risk) in adults. The conclusions that have great public health implications are: (1) there is no risk-free level of exposure to SHS; (2) many millions of children and adults are still exposed; and (3) eliminating smoking in indoor spaces fully protects non-smokers from SHS, but separating smokers from non-smokers and cleaning the air and ventilating buildings cannot eliminate exposure. The list of diseases with suggestive but insufficient evidence is much longer, and most notably includes childhood cancer (leukaemia, lymphoma, and brain tumour), onset of childhood asthma, and adult-onset asthma, breast cancer, nasal sinus cancer, stroke, atherosclerosis, and chronic obstructive pulmonary disease (COPD).

The 2002 IARC monograph

The 2002 IARC monograph concludes that involuntary smoking is a Group 1 carcinogen based on more than 50 studies in many countries, causing lung cancer with excess risk from spousal exposure of 20 per cent for women and 30 per cent for men (Aubin et al. 2011). Excess risk from workplace exposure is 16–19 per cent. The US Cal/EPA 2006 report concludes that SHS can induce asthma and can cause premenopausal breast cancer with an excess risk of 80–120 per cent and these are different from the 2006 USSG report. The 2009 IARC report has added that parental smoking can cause hepatoblastoma in offspring, that there is limited evidence for cancer of larynx and pharynx, and the evidence for female breast cancer remains inconclusive.

The estimation of deaths from SHS is less straightforward. It depends on what diseases are to be included, and what criteria (sufficient or suggestive evidence for causation) or reviews or meta-analyses are being used. Reliable SHS exposure data are not available in many places, and definitions of exposure vary in different surveys, which may not be based on a sample representative of a whole country. The WHO Global Burden of Disease Study estimates that SHS has caused 603,000 premature deaths in never smokers in 2004, including 166,000 from lower respiratory

infections, 1100 from asthma in children, 35,800 from asthma, 21,000 from lung cancer, and 379,000 from ischaemic heart disease in adults. Of all deaths from SHS, 28 per cent occur in children and 47 per cent in women. The report notes that current smokers may be especially susceptible because of high and close exposure or existing smoking-caused diseases (Oberge et al. 2011).

National or local estimates of mortality in non-smokers due to SHS are critically important for advocacy for legislation to ban smoking completely. The 2006 USSG report estimates that in 2005, SHS killed over 3000 Americans from lung cancer, 46,000 from CHD, and 430 newborns from sudden infant death syndrome. The 2007 China Tobacco Control report estimates that SHS killed more than 100,000 Chinese non-smokers. In Hong Kong, the results that SHS killed 150 catering workers from lung cancer and CHD (Hedley et al. 2006), and 1324 people (from stroke, heart disease, chronic lung disease, and lung cancer) each year (McGhee et al. 2005), had been used successfully in campaigns leading to the 2006 law amendments extending the total ban of smoking to all indoor workplaces, restaurants and bars, and many other public places. New results on SHS will contribute important new evidence for causal inference for asthma in children (Burke et al. 2012), stroke (Oono et al. 2011), TB disease (Lin et al. 2007; Slama et al. 2007; Leung et al. 2010), COPD (Yin et al. 2007; He et al. 2012), and acute respiratory symptoms (Monto and Ross 1978). The uncertainty about SHS and breast cancer remains (Pirie et al. 2008).

Adverse effects of SHS in current smokers

There is a paucity of data on the adverse effects from SHS in current smokers, mainly because of the exclusion of current smokers in most, if not all, studies on SHS. In Hong Kong, SHS exposure was reported to be strongly associated with increased acute respiratory symptoms and recent outpatient service use in adult current smokers (Lam et al. 2005) and to be associated with increased risks for persistent respiratory symptoms among adolescent current smokers (Lai et al. 2009). The main purpose of banning smoking completely in indoor workplaces is to protect workers, which is an occupational health issue. Opponents and the tobacco industry have advocated for smoking areas or smoking rooms, but workers who need to serve or clean inside smoking rooms are heavily exposed to SHS. A further argument is that smoker-employees can be deployed to work in smoking areas. Results on additional harms of SHS to active smokers can be used as a counter-argument. Also, both adult and youth smokers should be warned to avoid SHS, which may motivate some to support a totally smoke-free legislation and to quit smoking.

Chemicals and carcinogens

Tobacco smoke

Tobacco smoke is a very complex mixture containing more than 7000 chemical compounds (Rodgman and Perfetti 2009). Hundreds of these compounds are toxic and at least 69 are carcinogens. The list is expected to further increase. Also new additives have been and will continue to be added to cigarettes by the tobacco industry. These include various flavours (including menthol and fruits), and herbs or herbal medicine to attract special groups of smokers, such as children and youth, and people who believe in herbal medicine (Eriksen et al. 2012). The effectiveness

of using such information to warn about the harm of smoking needs to be evaluated. The main problem is that smokers do not feel any acute toxic effects from such chemicals because the level of exposure to each compound is low.

Second-hand smoke

SHS is a complex mixture of mainstream smoke (smoke inhaled and exhaled by the smoker) and side-stream smoke (from the burning end of the cigarette). Many of the toxic substances have a higher concentration in side-stream smoke than mainstream smoke, and it has often been mistakenly publicized that SHS is more harmful than active smoking. In terms of toxicity, this is not true because the toxic substances in SHS are greatly diluted by the ambient air before inhalation by the non-smokers. Hence, the exposure level of various compounds from SHS in a non-smoker is much lower than that in a smoker. In terms of the number of people affected to varying extents from mild irritation to deaths due to lung cancer or CHD, this statement can be true because of the widespread SHS exposure in non-smokers, and the absolute number of non-smokers, including children, is always greater than the number of smokers. Public health professionals should be mindful that messages are based on strong evidence and are effective.

Third-hand smoke

Third-hand smoke (THS) refers to the residual tobacco smoke pollutants on dust, surfaces, clothes, and human body after SHS has cleared. It can be re-emitted as gases as well as react with other pollutants such as nitrous acid to form tobacco-specific nitrosamines, some of which are carcinogenic (Burton 2011). Although the phenomenon of smelling residual smoke is not new, the coining of THS (Winickoff et al. 2009) has triggered much research and public interest. THS is accumulated with each cigarette smoked and remains for weeks. Young children are particularly at risk of exposure as they explore their home environment. However, no studies have linked THS exposure to physical harm and more studies on the chemistry and health risk of THS are warranted (Matt et al. 2011).

Risk perception of the public

The risk perception and tolerance of the public is often irrational and their resulting actions are not proportional to the magnitude of risks. Most people have zero tolerance to less toxic contaminants in foods, such as malachite green in fish, but relatively few are aware of the chemicals and carcinogens in tobacco smoke. More awareness of the harms of SHS has led to the rapid decline in tolerance to SHS. Non-smokers take various actions to avoid exposure and to complain about smokers who smoke near them. The past few decades have witnessed a change from total acceptance of smoking to zero tolerance among many non-smokers, especially in countries with comprehensive smoking bans.

The protection of innocent non-smokers, including children and women and employees, has been the major driver for smoke-free legislation. In China and many LMICs, awareness is low and even non-smoking physicians are not concerned about their own exposure to SHS (Lam et al. 2011). Tobacco control advocates need to learn from successful experiences in using SHS and in comparing the risk of tobacco smoke with other toxic compounds to change risk perception and motivate actions from non-smokers.

Although the harm of THS has yet to be shown, parents who are aware of that potential risk are more likely to adopt home smoking bans (Winickoff et al. 2009). This represents an opportunity to promote a totally smoke-free environment in the private home, the last frontier in the battle of tobacco control.

Warn about the dangers

Numerous surveys reveal that the knowledge about tobacco harms is often superficial. The earliest health warning required by governments or law was mostly a small and inconspicuous statement that smoking is harmful to health on tobacco advertisements (started in 1971 in the United States) or cigarette packs. Unfortunately, this is still the situation in many countries such as China.

Canada was the first country to require pictorial health warnings by law on cigarette packs in 2001. Its success has spurred many countries to follow suit. The Canadian Cancer Society 2012 report showed that 63 countries or jurisdictions and territories, covering 40 per cent of the world's population, require pictorial warnings (Canadian Cancer Society 2012).

The FCTC Article 11 requires that health warnings 'should be 50 percent or more of the principal display areas but shall be no less than 30 percent' (WHO 2003) and may be in the form of, or include, picture warnings. Many countries have done more than this minimum, with Australia having some of the largest warnings in the world at 75 per cent of the package front and 90 per cent of the back. From December 2012, Australia has also implemented plain packaging (Fig. 9.1.2) to prohibit tobacco company colours, logos, and design elements on the brand part of the package, and to standardize the shape and format of the package. The Constitutional challenges launched by the tobacco companies against the Australian

Government have been rejected by the High Court of Australia. Several countries (such as Canada, Norway, India, New Zealand, Turkey, and the United Kingdom) are planning to follow and these will be accompanied by legal challenges from the tobacco industry. Not all governments have the political will or the legal and other resources to defend against these. Nevertheless, the Australian success has served as a role model and the Australian court ruling will help governments, at least in common law countries, to defend and fight against new legal challenges.

Strong and increasing evidence shows that pictorial warnings are highly cost-effective in raising awareness and reducing tobacco use. The bigger the size of the warnings, the more effective they are. Some countries have also switched to the use of shocking images of diseased or damaged organs or dead bodies, including dead fetuses or babies. It is also important to start using the most striking pictures, have a set of more warnings (Australia has now a set of fourteen for plain packaging), and to require frequent rotations, with the printing costs totally borne by the tobacco companies and with minimal delay (as tobacco companies will produce many more packs before the law is passed and argue that they need many months or years to print new packs). The law should provide the health ministry the authority to change or update the pictures and warnings without having to amend the law. The warnings must be based on evidence that is considered sufficient for causation by most authorities. Information on pictorial warnings from all countries can be obtained from the Tobacco Labelling Resource Centre (n.d.) and the WHO warnings database (n.d.).

The tobacco industry has been fighting strongly in every country against such warnings, citing comments from smokers that they will take no notice of such warnings, and argues that printing such warnings increases production costs and affects the tobacco companies' rights to use their intellectual property to

show their brand names and logos, jeopardizing freedom of trade and expression. In the United States, despite the Food and Drug Administration Rule in June 2011 requiring pictorial warnings to cover 50 per cent of the package front and back as from September 2012, the implementation is on hold due to the successful legal challenge of the tobacco industry. The outcome of future legal proceedings is uncertain.

FCTC Article 11 (a) requires parties to ensure that ‘tobacco product packaging and labelling do not promote a tobacco product by any means that are false, misleading, deceptive or likely to create an erroneous impression. . .’, and that ‘These may include terms such as “low tar,” “light,” “ultra-light,” or “mild”’ (WHO 2003). Many countries still have tobacco products not complying with this article. The development and promotion of Chinese-style cigarettes as safer and healthier by the Chinese tobacco industry is particularly objectionable.

Although research has shown clearly that there is no completely safe form of tobacco, the tobacco industry continues to promote ‘safer’ cigarettes. There is evidence to show that such efforts have gained traction. The Global Adult Tobacco Survey in China (Chinese Center for Diseases Control and Prevention 2012) shows that more professionals and those with higher education believe that ‘light’ or ‘low tar’ cigarettes are safer. Because of the traditional belief in herbal medicine, adding such substances into cigarettes has been a major new effort by the Chinese tobacco industry to promote safer Chinese-style cigarettes.

Media campaigns

Mass media campaigns can be highly effective to raise awareness, motivate smokers to quit, and prevent young people from starting smoking. The effectiveness increases with the intensity of the campaigns, as well as the content and messages. Well-planned and sustained TV campaigns can reach most people, resulting in behavioural changes. Many antismoking videos have been systematically evaluated and confirmed to be effective in developed countries. However, the *WHO Report on the Global Tobacco Epidemic, 2011* showed a paucity of mass media campaigns against tobacco in many countries, especially in LMICs (Eriksen et al. 2012). The high costs of producing videos and broadcasting them on TV may be a factor, but could be overcome through global sharing of videos that have been shown to be effective, and by using alternative media such as YouTube and mobile phones. Further research, development, and evaluation are warranted.

Media campaigns are also needed to solicit public support for legislation and other government actions. Even when there is majority support for tax increases and smoke-free areas, objections from a small percentage of the population, sometimes leveraged on by the tobacco industry, can put great pressures on governments and legislators. Media campaigns to solicit public support need to be justified strongly by warnings that emphasize how many people, especially young people, will be killed by smoking, and such justification can further raise awareness.

Alternative ways to collaborate with the media should also be explored. Press conferences on local study results usually attract much media coverage, free of charge. The WHO’s World No Tobacco Day is an annual event that can be linked to other broad-based activities that can garner substantial media reporting and commentaries. International news, for example, on important findings from medical journals, or on resolutions from the WHO

or the FCTC can trigger the interest of local mass media. Public health advocates need to learn what the media want and how to work with them. For sustained effects, media campaigns need to be well planned and repeated, with updated results and new activities.

Monitoring tobacco use and prevention

Prevalence of smoking

Globally, about 20 per cent of all adults smoke cigarettes, consuming 5.9 trillion cigarettes in 2009. Even if smoking prevalence remains the same, tobacco consumption as a whole will increase due to the rising world population, especially in LMICs. China is the world’s largest producer and consumer of cigarettes, accounting for 38 per cent of global consumption. Because of its huge population and high smoking prevalence, China has the largest number of smokers (adults and youth) and smoking-induced deaths. The second to fifth highest cigarette-consuming countries are the Russian Federation, United States, Indonesia, and Japan.

Monitoring tobacco use is fundamental to our understanding of the extent of the epidemic, assessing the current and projecting the future burden of disease, and evaluating the effectiveness of prevention policies. The *Tobacco Atlas*, 4th edition (Eriksen et al. 2012), shows comprehensive world tables including prevalence in men and women, and in boys and girls. Sex-specific data are important since males and females have great differences in tobacco use. Time-trend data will become available for more countries. Interpretation of trend data where available should take into account variations in survey methods over time, and sampling errors.

In 1998, the WHO, US CDC, and Canadian Public Health Association initiated the Global Tobacco Surveillance System (GTSS) (Warren et al. 2009a) to help countries monitor tobacco use, using standardized methods in school-based and household surveys. The Global Youth Tobacco Survey (GYTS), Global School Personnel Survey (GSPS), Global Health Professions Student Survey (GHPSS), and Global Adult Tobacco Survey (GATS) started in 1999, 2000, 2007, and 2007 respectively (Warren et al. 2009b). The surveys are in progress, with greatest coverage for the GYTS as it started early. The GATS is a nationally representative household survey of men and women aged 15 or older. It includes: (1) tobacco use, (2) knowledge attitudes and perceptions, (3) cessation, (4) SHS exposure, (5) economics, (6) media, and (7) background characteristics. These surveys also provide essential data for monitoring prevention policies.

Other tobacco use

The tobacco epidemic started in the United Kingdom and United States with the invention of machines (in 1881 in the United States) for mass production of cigarettes, and the aggressive advertising and promotion of cigarettes by the tobacco companies, before the serious health hazards were widely known. Tobacco use, however, also includes kreteks (Indonesia), roll-your-own cigarettes (Europe and New Zealand), bidis (South Asia, mainly India), pipes (worldwide), sticks (Papua New Guinea), water pipes (North Africa, the Mediterranean region, and parts of Asia), cigars (worldwide), and various forms of smokeless tobacco, including chewing tobacco (worldwide), moist snuff (Scandinavia and United States), dissolvable smokeless tobacco products (high-income countries), and dry snuff (Europe) (Eriksen et al. 2012).

The International Tobacco Control Policy Evaluation Project

The ITC Project is the first international cohort study on the psychosocial and behavioural impact of key national level policies of the FCTC (International Tobacco Control Policy Evaluation Project n.d.). ITC includes 20 countries with 50 per cent of the world's population and 70 per cent of the world's tobacco users and covers:

- ◆ Health warning labels and package descriptors
- ◆ Smoke-free legislation
- ◆ Pricing and taxation of tobacco products
- ◆ Communication and education
- ◆ Cessation
- ◆ Tobacco advertising and promotion.

Stages of tobacco epidemic

The patterns of smoking and tobacco-induced diseases, particularly lung cancer, vary greatly in different countries. Lopez et al. (1994) defined four stages of the tobacco epidemic, based on developed countries like the United Kingdom, United States, and Australia. Smoking prevalence rose rapidly since the 1900s, first in men peaking in the 1950s, followed by women about two decades later reaching a lower peak, and then declined since the 1960–1970s, after large numbers of smokers stopped. Tobacco deaths in men lagged this, peaking about three decades later in the 1980s and then declined as a result of increased cessation, whereas in women, tobacco deaths continued to increase or plateau into the present century. This four-stage model highlights the long delay (about three decades) between widespread smoking and its full effects on mortality. It has been applied to other countries or regions, with sub-Saharan Africa in Stage 1, Latin America in Stage 2, Eastern Europe in Stage 3, and the United Kingdom in Stage 4.

A recent review of the model after two decades showed that in developed countries, the prevalence of smoking has continued to decline in both sexes and the proportion of deaths due to smoking has declined in men and continues to increase or plateau in women (Thun et al. 2012). Latest findings also support that tobacco deaths in the United States have plateaued in men but continue to rise in women (Thun et al. 2013). The model generally applies to men in developing countries but cannot predict when (or if) women will begin smoking in large numbers. Thus, modified criteria and separate models are needed to describe the epidemic entirely for men and women in developing countries. The long lag between peak tobacco deaths and peak tobacco consumption is a key reason for the lack of urgent action among governments and politicians.

Smoking in women

A limitation of this model is that it does not take into account the history and timing of tobacco control measures. Data from Hong Kong (Lai 2012) show that its downward male smoking trend (from 39.7 per cent in 1982 to 19.9 per cent in 2010) appears to be similar to Australia and the United States, but its female trend from 5.6 per cent to 3.0 per cent does not follow the model. About three decades ago, tobacco control advocates in Hong Kong predicted a great rise in female smoking prevalence, which did not

happen. This could be due, at least partly, to the early introduction of tobacco control measures including a 300 per cent increase in tobacco tax in 1983 (and 100 per cent in 1991), and legislation restricting (1982, 1990, 1992, 1998, 1999, and 2007) and eventually banning tobacco advertising (2008).

Enforce bans on tobacco advertising

It is recognized that a comprehensive ban on advertising, promotion, and sponsorship would reduce the consumption of tobacco products. Before restrictions on tobacco advertising in the mid 1960s, many high-income countries, such as the United Kingdom and United States, witnessed aggressive advertising especially targeting women. Now, 103 countries have some restrictions on tobacco marketing, but only 24 countries (10 per cent of the world population) have banned all forms of direct and indirect advertising (WHO 2013a).

Partial restrictions are ineffective as the tobacco industry has many ways to bypass them. In Hong Kong, where all forms of tobacco advertising are banned but the display of cigarettes at retailing shops and newspaper stands is allowed, the tobacco companies pay large sums of money to expand the display area with spotlights on individual cigarette packs. The government has difficulty prosecuting this as newspaper stand and shop owners will protest such actions. LMICs should aim to move directly to a total ban. Some African countries have done so before the multinational tobacco companies have gained a foothold. Other countries like Thailand have banned the display of cigarettes.

Banning of indirect advertising is very difficult as some cigarettes share the same brand as non-tobacco products (brand stretching). In China, a famous and very expensive cigarette brand from Shanghai was named, many decades ago, 'Zhong Hua' meaning China. The tobacco company launched a campaign of 'I love Zhong Hua', featuring two Chinese characters in the same format as the cigarette logo. Some Chinese brands are named after a famous place or an animal (such as Panda). Bypassing advertising bans in this manner is increasing, but many governments have no experience or resources to prosecute them or the confidence that they will win in court.

Banning of sponsorship is the most difficult of all. The FCTC defines this as 'any form of contribution to any event, activity or individual with the aim, effect or likely effect of promoting a tobacco product or tobacco use either directly or indirectly' (WHO 2003). Victoria in Australia was the first to use tobacco tax proceeds to establish a health foundation in 1987 to replace tobacco sponsorship. This successful example has been cited by tobacco control advocates in many countries, but few have succeeded (such as Thailand). Many organizations' events and activities, politicians, legislators, researchers, and other individuals are receiving tobacco sponsorships/money. They are unlikely to support stringent tobacco control measures, and may join the tobacco alliance directly or indirectly. Governments need to ban offering and receipt of all forms of tobacco sponsorships. Interim measures could include legislation requiring disclosure and policies forbidding such sponsorships. To help implement and enforce comprehensive bans on tobacco advertising, promotion, and sponsorship, the WHO has developed a 3-day training workshop for LMICs (World Health Organization and International Union Against Tuberculosis and Lung Disease 2011).

Protect people from tobacco smoke

A major breakthrough in tobacco control was the designation of smoke-free areas to protect people from SHS, and the related non-smokers' rights movement starting in the 1980s in the United States. Banning of smoking in public places by law has been introduced, often progressively from a partial to total ban, and is expanding to include all public places (from indoor to outdoor) and all indoor workplaces (public and private). Further bans were introduced in outdoor areas in some countries, such as busy streets in Japan. With overwhelming public support, Singapore has recently extended the smoking bans to the common areas of residential buildings, covered walkways, pedestrian bridges, a 5-metre radius from the edge of bus stops, and outdoor compounds of hospitals. The number of people protected by comprehensive smoke-free laws has doubled from 2008 to 2010, but 89 per cent of the world's population remain unprotected (Eriksen et al. 2012).

Public support is strong only in countries where awareness of the harms of SHS is high together with strong political will of governments. The tobacco industry has worked to oppose this, building alliances with smokers' rights groups and others who may be adversely affected, such as the hotel and catering industry. Some restaurant workers or their unions are mobilized by their employers, with support from tobacco companies, to protest. The tobacco industry will lobby governments and legislators and repeatedly argue that banning smoking in restaurants and bars will result in loss of customers, revenue, and jobs. However, in all jurisdictions, implementation of smoke-free laws has mostly resulted in no changes or increased restaurant sales, and savings in cleaning costs and reduction of fire risks.

A total ban is needed to eliminate SHS exposure. However, the tobacco industry is often successful in exploiting loopholes in such laws (such as no legal liability or penalty for venue owners or managers if they allow smoking in their statutory smoke-free areas in Hong Kong). Many restaurant owners still believe that their business will suffer from total smoking bans, particularly in LMICs. Public health advocates must distinguish between the tobacco companies and venue owners even when they form an alliance. Mass media and other campaigns, such as motivating students and other non-smokers to demand smoke-free dining areas, are effective ways to change the minds of some restaurant owners and workers. Some will never be convinced but all will want a level playing field such that any new laws should equally apply to all venues; allowing some restaurants to have smoking areas but not others will not work.

A national smoke-free law is needed but in China, only some major cities have started to introduce local smoke-free legislation. However, enforcement is weak, penalties for violation low, and compliance is expectedly unsatisfactory. Mass media campaigns are needed before the implementation of the new law. Initial law enforcement with substantial penalties is essential to convince the public and venue owners about the government's seriousness. Effective enforcement of comprehensive smoke-free legislation saves lives by reducing heart attacks, increasing quitting in the population, and reducing smoking among employees (Glasgow et al. 1997).

Raise taxes on tobacco

Raising taxes is the most effective way to reduce tobacco consumption quickly. Repeated and sufficiently high increases in tax drove

the decline in consumption especially in high-income countries a few decades ago. On the other hand, with economic development and increasing incomes in LMICs such as China, the reduction in real tobacco prices has substantially contributed to increasing consumption. High prices are particularly effective in preventing the uptake of smoking in the young and reducing consumption among low-income people, with more quitting in both groups. Strong evidence has come from both high- and LMICs, such as the United Kingdom, South Africa, Morocco, and Israel (Eriksen et al. 2012). A more recent example is from France, where tripling the price of cigarettes has halved consumption and doubled government revenue in 2003–2004 (Gallus et al. 2006).

The seminal World Bank report in 1999 states that all evidence from high- and LMICs shows that price increases are highly effective in reducing demand. The statement that 'On average, a price rise of 10 percent on a pack of cigarettes would be expected to reduce demand for cigarettes by about 4 percent in high-income countries and by about 8 percent in low- and middle-income countries' (World Bank 1999) has been widely cited. The *Tobacco Atlas*, 4th edition (Eriksen et al. 2012) shows different degrees of reduction, 2–6 per cent in high- and 2–8 per cent in LMICs. The model in the World Bank report shows that raising prices by 10 per cent worldwide would result in 40 million smokers quitting in 1995 and preventing at least 10 million deaths. This estimate is conservative because if one in two smokers will be killed by tobacco, 40 million current smokers quitting would prevent about 20 million deaths. As price increases will also reduce uptake of smoking in young people, there will be further reduction of deaths in the more distant future.

Big variations in the excise tax as a percentage of cigarette prices are shown in the *Tobacco Atlas*. The WHO recommends that excise tax should reach at least 70 per cent of the retail price but only five nations have achieved this standard (Eriksen et al. 2012). The World Bank proposes that taxes should account for two-thirds to four-fifths of the retail price (Mackay et al. 2006). Tobacco tax increase can also generate additional income for governments. As of 2010, at least 166 WHO Member States have imposed a tobacco excise tax, and at least 27 of them used a portion of the tobacco tax revenue for health purposes. Numerous economic analyses have shown that the economic costs of tobacco, including lost productivity and health and other expenditures from tobacco-induced disease burden, are greater than tobacco tax income. The 2012 Asian Development Bank report estimated that in China, India, Philippines, Thailand, and Vietnam, a 50 per cent price increase would reduce tobacco deaths by over 27 million, and generate over \$27 billion additional revenue annually (Asian Development Bank 2012).

Given these data, it is not clear why most governments have not implemented the WHO recommendation of at least 70 per cent, even after they have ratified the FCTC. Collusion between the tobacco industry and government officials, the loss of tobacco tax revenue if consumption falls sharply, or inadequate funding allocation for tobacco control in LMICs are possible reasons. More research is needed to find the root causes for this, and effective ways to convince governments to do so.

Any tax increase is not welcomed in general by the public and may lead to dissatisfaction towards governments, which could result in protests and unrest. The economic argument that reduction of tobacco use can save healthcare expenditures has little

direct immediate impact because such savings are only realized in the future. A very strong argument from opponents is that high taxes will result in increased smuggling, making cheaper illicit cigarettes more available to many low-income smokers especially youth. However, a recent report showed that tax increases in the United Kingdom have not led to increased smuggling.

Tobacco industry

In celebrating the fifth anniversary of the FCTC, WHO Director General Dr Margaret Chan said, 'the tobacco industry is ruthless, devious, rich and powerful. As we all know, neither WHO nor public health is rich, but with the Framework Convention now in place, we are indeed powerful' (WHO 2010). It is the only industry that has been openly and repeatedly discredited, condemned, and shamed by WHO.

The tobacco industry is dominated by several multinational tobacco companies. The China National Tobacco Corporation is the largest state-owned enterprise producing the greatest number of cigarettes in the world. Despite the progress in tobacco control in some countries, and the FCTC, the tobacco companies remain some of the most profitable in the world (Eriksen et al. 2012).

Tobacco company documents

Research and numerous reports have exposed the tobacco industry's various anti-public health measures. Most of the findings are based on the analysis of millions of pages of internal tobacco company documents exposed since 1994 and during litigation proceedings against the tobacco companies in the 1994 seminal judgement in the United States, now deposited in Minnesota, United States and Guildford, United Kingdom (Mackay et al. 2006; Shafey et al. 2009). These documents are still under-researched but are now easily accessible for public health professionals and researchers, particularly those interested in what the tobacco industry had said about their countries or regions and strategies including the targeting of children or women. They provide insights into the varied strategies employed by the tobacco industry to promote the continued use of tobacco among different communities and population segments (Mackay et al. 2006; Shafey et al. 2009; Eriksen et al. 2012; World Health Organization 2013b).

Tobacco corporate social responsibility

The tobacco companies spend huge sums of money in funding smokers' groups, tobacco associations and institutes, and other alliances to oppose tobacco control measures; funding researchers to challenge the evidence of tobacco harms particularly from SHS; funding research but suppressing or distorting unfavourable results; and funding government and non-government organizations and various events or programmes on education, arts, culture and sports, environmental protection, and medical, health, or rehabilitation programmes to promote cigarette brands and corporate image and to buy in supporters or silence potential opponents (World Health Organization 2013b).

Youth Smoking Prevention (YSP) programmes, funded by the tobacco industry, are particularly deceptive and troubling. These are ineffective as they focus on young people only and portray smoking as an adult habit thus making it more appealing for adolescents. YSP programmes have attracted NGOs interested in adolescent health, community leaders, and schools who do

not understand their motivation. This has created much confusion and frustration for tobacco control advocates, who need to be extremely cautious about how to expose the tobacco connections and ineffectiveness of YSP programmes, yet not to alienate those who have been deceived. The WHO booklet from Western Pacific Regional Office on YSP is an invaluable resource (WHO 2003). How should youth programmes be organized that can be distinguished from YSP? In Hong Kong, the strategy is to promote the WHO booklet (Ho et al. 2010) and to launch youth quitting programmes instead of smoking prevention programmes. It is useful to bear in mind and emphasize that the great majority of young people do not smoke. Over-emphasis on youth smoking may result in over-estimation of peer smoking in adolescents, which can increase adolescent smoking (Ho et al. 2010).

The tobacco industry has not changed, as evidenced by their current efforts to use litigation and legal threats against governments that are planning or have introduced new control measures. The *Tobacco Atlas*, 4th edition, lists legal challenges against tobacco control measures by the tobacco industry in 18 countries (Eriksen et al. 2012). The tobacco companies will launch more of these in more countries. Some tobacco control advocates in the West have called for government to buy the tobacco companies to control them. However, the example of China's national tobacco monopoly indicates that the result could be even worse. Some tobacco control advocates in China have called for the separation of the administration arm, which can then monitor and control the enterprise arm more independently.

Should governments sue the tobacco industry? A major landmark was the success of the US government's 1999 lawsuit which resulted in the major tobacco companies paying settlements of US\$206 billion over 25 years to 46 states to compensate for government spending on smoking-related healthcare (Gruber 2001). The number of anti-tobacco legal cases has been increasing but only slowly. The ultimate legal defeat of the tobacco industry would be to make tobacco illegal.

WHO FCTC

The FCTC is an evidence-based treaty and a paradigm shift in developing a regulatory strategy on demand reduction and supply issues (WHO 2003). The success of the FCTC has prompted and inspired public health advocates to call for similar treaties, such as a framework convention on alcohol control (FCAC) (Casswell and Thamarangsi 2009; Lam and Chim 2010). The FCTC is a readable, action-oriented document that can be used by governments, public health professionals, and the public. It has led to a global movement and is a strong lobbying document to pressurize governments to comply with the international treaty that they have ratified. The FCTC only stipulates the minimum that governments must do, and Australia's plain packaging in 2012 clearly shows that more can be done.

Countries that have not ratified the FCTC are under great pressure to ratify. Many governments have not yet fulfilled their obligations to comply fully with the FCTC, and these are reported regularly in WHO MPOWER reports.

The FCTC is governed by the Conference of the Parties (COP), which comprises all Parties (countries or jurisdictions) to the Convention. It reviews and makes decisions to promote its effective implementation, and adopts protocols, annexes, and amendments

to the Convention. Starting from COP3, the regular sessions of COP are held biennially.

The Protocol to Eliminate Illicit Trade in Tobacco Products, in pursuance of FCTC Article 15, is the first protocol adopted by the COP as effective, appropriate, and comprehensive domestic and international responses to eliminate all forms of illicit trade (World Health Organization Framework Convention on Tobacco Research 2012).

Framework Convention Alliance

The FCTC is not just for health ministries or governments. NGOs have played key roles from the beginning of its negotiation, and their influence is expanding. The Framework Convention Alliance (FCA) created in 1999 has over 350 organizations from more than 100 countries. It is a civic society alliance whose mission is to help develop and implement the FCTC as the basis for effective global tobacco control (FCA n.d.). The FCTC has become the benchmark for the evaluation of the performance and effectiveness of tobacco control measures of parties, countries, or regions. For example, those who have been performing badly are being shamed by The Dirty Ashtray Award by civil society; China received one such award for making excuses not to print warning pictures on cigarette packing at COP3 in 2008.

FCTC and UN Political Declaration on NCDs

The FCTC has laid the foundation for the 2011 UN Political Declaration for the control of NCDs, and now the reverse is happening. As a follow-up to the UN Political Declaration, WHO is consulting on the development of the NCD Global Monitoring Framework (WHO 2012b) and the Global Action Plan on NCDs (2013–2020) (WHO 2012c). After lobbying by the FCA, the draft Global Action Plan on NCDs (10 October 2012) now explicitly promotes the FCTC and urges all WHO Member States to accelerate its implementation. While the NCD Global Monitoring Framework includes a tobacco smoking target (voluntary, to be determined), FCA further advocates to monitor specific process and impact indicators on the implementation of FCTC policy measures. There will be rapid and major developments on all these fronts.

Research and evaluation

The FCTC is based on solid research conducted mostly in high-income countries. Evidence from LMICs is inadequate. Progress in policies and implementation in some countries has been rapid and great, and previous experiences and evidence can become outdated while the impact of new measures need to be rapidly evaluated to guide further action. In countries with slow progress, the lack of funding and research is very serious. Their needs for local data and evidence are more urgent and should be most relevant for local policies and implementation. Further and relevant research is needed for all countries to support and evaluate the implementation of the FCTC. The Global Network of the Society for Research on Nicotine and Tobacco (SRNT) has published a series of papers in a themed issue of *Nicotine & Tobacco Research* on the research requirements and needs for all the FCTC articles to support specific policies and practices (Leischow et al. 2012). This is a most thorough analysis of the state of science to provide new directions and priorities for research. A commentary

by Mackay emphasizes that ‘advocates and activities MUST keep their feet firmly based in science, and never stray from that science’ but ‘The need to bridge the existing gaps between research, policy, and practice appears to be a global phenomenon’ (Mackay 2013).

Offer help to quit tobacco use

Quitting smoking saves lives and the earlier the better. In cancer patients, increasing evidence shows that quitting smoking can improve the effectiveness of treatment and survival and more successful trials are needed to motivate HCPs to help such patients to quit (McBride and Ostroff 2003; Parsons et al. 2010).

Most successful former smokers quit without pharmaceutical therapy or professional services (‘cold turkey’). They do have different experiences including past failures that deserve further study. On the other hand, effective treatments are available which have helped many to quit. The pursuit for more effective pharmaceutical treatments, including nicotine vaccination will go on, as the existing treatments are expensive and failures common.

The 1990 USSG report on smoking cessation was the first comprehensive review about the benefits of quitting (US Department of Health and Human Services 1990). The excess risk of ischaemic heart disease is reduced by half after stopping for 1 year, but it takes 10 years of quitting for lung cancer risk to reduce to 30–50 per cent of continuing smokers. The 2007 IARC report on risk reversal, the most recent comprehensive review, concludes that the evidence is adequate for: (1) lower risk in former smokers and (2) lower risk with prolonged abstinence for lung, laryngeal, oral, oesophageal (squamous cell), pancreatic, bladder, and cervical cancer (seven items), and CHD incidence and death in subjects with or without the disease, cerebrovascular incidence and death in those without established disease (three items), and cough and phlegm, decline in forced expiratory volume in 1 second in healthy subjects and those with mild to severe disease and COPD mortality (five items). For overall mortality, those ‘stopping at 60, 50, 40 or 30 years of age gain, respectively, about 3, 6, 9 or almost the full 10 years of life expectancy, in comparison with those who continue to smoke’ (IARC 2007). Those who stopped smoking before middle age, at about 20–30, avoid nearly all of the future mortality risks from tobacco (Doll et al. 2004; Pirie et al. 2013).

Quitting or preventing uptake?

Uptake prevention and quitting have different target subjects and need different strategies. Most people intuitively support very strongly the prevention of smoking in children and young people and believe that this is the *most* important measure. They want more health education against youth smoking and consider health education in schools the most important action. Such a belief is exploited by the tobacco industry’s YSP programme.

The 1999 World Bank report states that if quitting results in reducing adult cigarette consumption by half by the 2020s, about one-third of tobacco-related deaths in the 2020s would be prevented and almost half would be prevented thereafter, preventing 20 or 30 million tobacco deaths in the first quarter and 100 million in the second quarter of this century. If young smokers are reduced by half by the 2020s, hundreds of millions of tobacco deaths would be prevented after 2050. This would prevent none of the 150 million tobacco deaths in the 2020s, about 10–20 million

out of 300 million in the second quarter of the century. Hence, quitting will prevent more deaths more quickly in the first half of this century than that from preventing young people from starting, although the latter is also important for preventing deaths in the second half of the century.

Nicotine dependence or habit

Smoking is often wrongly described as a habit or a personal choice. Nicotine is strongly addictive and most smokers are both nicotine and psychosocially dependent. The Fagerstrom test is the most commonly used test to measure nicotine dependence (Heatherton et al. 1991). But the term 'nicotine addict' is seldom used to describe heavily nicotine-dependent smokers and the term 'treatment of nicotine dependence' is much less frequently used than 'smoking cessation therapy'. HCPs need to understand why smokers frequently fail in their attempts to quit, or relapse after a short time.

Smoking cessation interventions include smoking cessation clinics (which vary from simple counselling to specialized in-hospital treatment) or telephone quitlines, smoking cessation advice and counselling during routine consultation, and pharmacological aids and therapies. Most of these have been confirmed by numerous trials to be effective and more cost effective than other medical treatments. The Cochrane Library should be consulted for updated reviews and conclusions (Cochrane Review Groups n.d.). Effectiveness means greater quit rates after interventions than no interventions, but failures occur more often than successes.

The seminal randomized controlled trial by Russell (1979) that brief advice by general practitioners in the United Kingdom increased the quit rate from 0.3 per cent to 3.3 per cent has led to a strong argument that if all physicians can spare a little time advising patients to quit, even though the absolute quit rate is low, many smokers will benefit, resulting in major community impact. Thirty years later, the review by Aveyard and Foulds (2009) showed that a brief intervention of at least 1 minute is effective (versus no intervention). However, most clinicians are too busy to spare even 1 minute and many feel incompetent. They also do not have any incentive, support, or pressure to do so. Such barriers are still common in both high- and LMICs. To address these issues, a simple 30-second pilot intervention emphasizing 'one in two risk' was recently conducted in China with promising results (Lin et al. 2013).

Do most smokers want to quit?

The 2008 MPOWER report states 'Among smokers who are aware of the dangers of tobacco, three out of four want to quit' (WHO 2008) without specifying the country. But the reference (Jones 2006) indicates that this statement is based on a survey of US adults in 2006 and it should be noted that the denominator is *not* all smokers. While this may be true in countries at the late stage of the tobacco epidemic, the Global Adult Tobacco Use Surveys in China and other LMICs show that most smokers do not intend to quit (Cooper et al. 2010; Chinese Center for Diseases Control and Prevention 2012). A deeper understanding of the smoker's intention and the strength of their motivation or determination to quit or reduce smoking can guide public health policies and planning on cessation services. Social support from family, friends, co-workers, and employers is needed.

Clinical or public health approaches?

During the early years of tobacco control, the emphasis was mostly on public health measures such as legislation and taxation. These measures were deemed more effective than clinical services that target individual smokers, especially since few physicians or HCPs were prepared to act. The high costs of clinical services also rendered them less cost-effective. The controversy over these two approaches has become more complex as effective pharmaceutical treatments have become available (Chapman and MacKenzie, 2010; West et al. 2010). While the Bloomberg Initiative to Reduce Tobacco Use does not support smoking cessation services for individuals, these services are rapidly developing elsewhere, such as in the United Kingdom. More quitlines and international quitting campaigns such as Quit and Win have also been developed. The WHO has provided detailed guidelines for setting up and running national quitlines especially in LMICs (WHO 2011).

Quit rates for all the existing nicotine replacement therapies and drugs are not high as most users fail to quit after receiving treatment. The costs are high and adherence is low. The high failure rate is demoralizing. The 5As in the United States (ask, advise, assess, assist, arrange) has been one of the most referenced guidelines (Cornuz and Willi 2008) but these are too demanding for busy HCPs. Simpler guidelines or methods are recommended such as ABC in New Zealand (McRobbie et al. 2008). Development and randomized controlled trials of shorter advice of less than 1 minute are needed (Lam 2012; Lam et al. 2012).

Public health professionals need to understand that the clinician's job is primarily treatment. If clinicians are frustrated by failures of smokers to quit despite their efforts, they should be made more aware and become more motivated to support or join in public health advocacy campaigns. Clinicians and their professional organizations are strong allies for public health in general and tobacco control in particular. Public health professionals should collaborate with clinicians to develop more effective measures to increase cessation in individual smokers and in the population.

Pilot cessation clinics

In LMICs, many physicians are smokers, and they seldom advise their patients to quit smoking. Some smoke quite openly, if smoking is allowed in the healthcare settings, such as hospitals. Even non-smoking HCPs are mostly inactive (Lam et al. 2011). In recent years in China, smoking cessation clinics have been established in many hospitals as a requirement for designation as smoke-free hospitals. This was also done to comply with the FCTC. But most clinics have attracted few smokers, from the hospitals and the community. Opening a clinic without strong support from top management, including adequate funding, capacity building, and incentives for HCPs, will not work. Lacking strong tobacco control measures in the greater environment, and funding to promote the cessation clinics, the wait for smokers to come will be in vain.

As a first step, introducing a pilot smoking cessation clinic with provision of training and support can motivate a hospital and its management and some HCPs to become interested, firstly in treatment, and then in tobacco control in general. The pilot can act as a springboard, bringing tobacco control advocates into a hospital to train interested HCPs in both smoking cessation intervention and tobacco control advocacy. With a core of trained HCPs, the clinic

can become a focal point for further actions, such as implementation of smoke-free hospital policy, and extending beyond the clinic and the hospital into the community, such as supporting smoke-free workplaces and tobacco tax increases or public education campaigns in the neighbourhood. The clinic can also motivate the smoking HCPs to quit smoking, or to discourage smoking within the hospital, and become a training site for other staff and medical and other students.

On the other hand, public health professionals should work closely with clinicians to set up strategies for proactive approaches to help smokers outside the clinic, such as in the wards and outpatient departments and to promote quitting and tobacco control within and beyond the hospital to develop the cessation clinics into tobacco control advocacy centres. Systematic evaluation of the impacts and sharing of experiences are essential for further improvements and development.

Smoking cessation can also act as the 'carrot' for the 'stick' of government proposed policies to expand smoke-free places and increase tobacco tax. Tobacco control opponents often argue that the policies are unfair to smokers and unkind to the poor, leaving the smokers nowhere to smoke and depriving the poor of their only affordable pleasure. Many government officers have difficulty responding to such allegations. If government-subsidized free smoking cessation services are offered, the simple answer is that smokers are encouraged to quit using the pilot clinics. If they quit, they will not need to find permissible places to smoke and will save a lot of money for more healthy and pleasurable commodities for the whole family.

Some government officers also feel that because there are so many smokers, they will not have the resources or capacity to open an adequate number of cessation clinics to cope with the demand. Some even feel that smokers should pay for the services, using the money saved from buying cigarettes. In reality, only a small percentage of smokers will visit cessation clinics, and many more will quit by themselves, often with social support from the family and others. A few cessation clinics or a quitline should therefore be sufficient and the sudden increase in visits and calls serves as an indicator of the effectiveness of the new control measures. Furthermore, if all or even a small percentage of the excess revenue arising from the increase in tobacco tax is used to support smokers to quit and to promote quitting, governments will have a strong justification that part of the money obtained from smokers will be used to benefit the smokers.

Quitting or smoking reduction?

Many smokers who claim that they have reduced smoking may not be reporting the truth, and total abstinence is the only proven way for the benefits to be realized. Smoking reduction may be a distraction from total abstinence. Evidence for the benefits of smoking reduction and organized or regular services or campaigns focusing only on smoking reduction are scarce. But there are many smokers who do not want to quit completely but are willing to reduce smoking. New evidence has shown that helping such smokers can increase quit rate and reduction (Chan et al. 2011). Smoking cessation campaigns and services will not attract such smokers. New approaches are needed to assess the needs of smokers who are not willing to quit and to recruit and help them to reduce, and to follow up and evaluate further whether such approaches are effective in eventually helping the smokers to quit.

Controversies of harm reduction

Evidence, mainly from Sweden, that smokeless tobacco users have a lower risk of lung cancer and other diseases than cigarette smokers, has triggered debates about switching from cigarettes to smokeless tobacco as a harm reduction measure (WHO 2003). Opponents to such switching argue that it does not reduce the harm substantially, and promotion of switching can be seen as promotion of smokeless tobacco use resulting in reduced motivation to quit. It may also increase uptake of smokeless tobacco use in young people. More broadly, such strategies effectively entail the replacement of nicotine from tobacco use with nicotine-containing products (Foulds and Branstetter 2012). The debate is continuing, but the tobacco companies are moving fast to promote smokeless tobacco and develop other nicotine products. The UK National Institute for Health and Care Excellence (NICE) has released draft guidance for consultation, which includes NRT and e-cigarettes but excludes smokeless tobacco (NICE 2013).

Endgame or endless war?

The rapid reduction of smoking prevalence in some countries, the increasing impact of the FCTC, and strong political will of some governments have led to optimism and aspirations that a smoke-free country has become reachable within 20 years. The Bhutanese 2004 law aims to end tobacco sale, the 2010 Finland Tobacco Act aims to end tobacco use, and the US government has the 'vision of a society free from tobacco-related death and disease' (US Department of Health and Human Services 2012). In March 2011, the New Zealand government committed to become an essentially smoke-free nation by 2025 and the website has much information on policies and actions (Smokefree New Zealand 2025 n.d.).

On the other hand, the war against tobacco and the tobacco industry has just begun in many LMICs, where political will is lacking to fight wholeheartedly. For the pessimists, new tobacco control advocates and younger public health professionals, this appears to be an endless war, sometimes with more battles lost than won. However, a careful review of past battles, globally and in many countries with more advanced tobacco control measures, indicates many more victories, every one of which had been fought initially by only a few dedicated and courageous people (Lam 2013). Fighting a battle today anywhere is much easier than it was a few decades ago. We now have the FCTC and another new international treaty under the FCTC (COP5) and more will be forthcoming. We also have the UN Declaration against NCDs (and tobacco). When we are facing the aggressive challenges from the tobacco industry including suing governments, we know Big Tobacco is desperate and that eventually, the public health goals will prevail, despite occasional loss, compromises, and setbacks. For public health professionals, our experiences in tobacco control will guide us to tackle the other three risk factors. If tobacco cannot be controlled successfully, the chances for success in controlling the other risk factors will be slim. Fighting against the risk factors and NCDs will be an endless war, as promoting health and well-being of all people will be our never-ending mission.

Acknowledgements

We thank Dr L. Xu for her help in literature search, referencing, and preparing the figures. Our sincere gratitude goes to Professors

J. Mackay and R. Peto, who have been inspirational and supportive to our research and public health advocacy on tobacco control.

Public health aspects of illicit psychoactive drug use

Don Des Jarlais, Jonathan Feelemyer,
and Deborah Hassin

Illicit psychoactive drug use and public health: an introduction

The misuse of psychoactive drugs is a major public health problem in many countries throughout the world. Nicotine (in the form of tobacco products) and alcohol are the most commonly used and misused psychoactive drugs, and account for the greatest mortality and morbidity related to psychoactive drug use. Since nicotine and alcohol are discussed in Chapters 9.1 and 9.3, this chapter focuses on illicit psychoactive drugs, in particular opiates such as heroin, cocaine, and amphetamine-type stimulants (ATS), which cause major public health problems even if they are not of the magnitude of the problems caused by nicotine and alcohol.

The United Nations Office on Drugs and Crime (UNODC) compiles annual estimates of the prevalence of the use of various illicit psychoactive drugs (UNODC 2012) and assesses trends over time. In the most recent *World Drug Report* published in 2012, the UNODC estimated that in 2010, between 3.4 and 6.6 per cent of the adult population (persons aged 15–64) used an illicit drug in the previous year. Of these, some 10–13 per cent of drug users were considered to be problem users with drug dependence and/or drug-use disorders.

With respect to the use of specific illicit drugs, the UNODC (2012) estimated that cannabis was by far the most commonly used drug, with 2.6–6.0 per cent of adults (120–420 million adults) having used it in the previous year, followed by opioids, cocaine, and ATS that were each used by approximately 0.5 per cent of adults (35 million). These estimates have been relatively stable over the previous 5 years.

The Global Burden of Disease project recently estimated the numbers of deaths and of disability-adjusted life years (DALYs) lost attributable to illicit drug use for 1990 and 2010. Attributable deaths increased from 68,577 in 1990 to 157,805 in 2010 (Lim et al. 2012). DALYs also increased substantially during the same period, from 15,171,000 to 23,810,000. Men suffered much greater effects than women; in 2010, there were 109,420 deaths attributable to drug use among men and 48,365 deaths among women.

Deaths and DALYs attributable to drug use were quite modest compared to deaths and DALYs attributable to tobacco smoking and alcohol use. For the 2010 analysis, there were 5,695,349 deaths attributable to tobacco smoking and 4,860,168 deaths attributable

to alcohol use. Similar to the effects of drug use, the effects of tobacco smoking and alcohol use were much greater among men than women.

Despite the modest numbers of adults who use illicit drugs, they generate many costs to society, including lost productivity, increased disability and deaths, disruption of family and other social relationships, and costs of increased law enforcement and incarceration. This chapter will focus on health-related aspects of illicit drug use. Approximately 0.5–1.3 per cent of all deaths among adults in the world are related to illicit drug use and 4 per cent of adult deaths in Europe (European Monitoring Centre for Drugs and Drug Addiction 2011; UNODC 2012).

Basic biological and psychological research over the last two decades has led to a greatly increased understanding of the mechanisms of drug use. A review of this research is beyond the scope of this chapter, but it may help to state a few general summary statements as a background: (1) there is great individual variation in reactions to different drugs; (2) repeated drug use does lead to observable changes in brain systems, particularly in those systems related to reward or reinforcement of behaviours; (3) the major problem in treating substance use disorders (SUDs) is not the initial ceasing to use drugs, but avoiding relapse back to use; (4) while it is not yet appropriate to think in terms of a ‘cure’ for SUDs, there are effective treatments to manage the condition; (5) there are very important differences in the effects of different drugs but also very important similarities in the compulsive use of different drugs; and (6) increased knowledge of the effects of various drugs has uncovered great complexity rather than uncovering any simple methods for ameliorating the harmful effects of drugs on the brain and behaviour. Thus, while knowledge of drug effects and their mechanisms is likely to continue to increase rapidly, it is unrealistic to expect that there will be any ‘magic bullet’ breakthroughs for either the prevention or treatment of SUDs in the near future.

Current global patterns in drug use

Geography is not necessarily destiny with respect to what drugs a person might use, but there are strong geographical patterns in the use of different drugs. The information on geographic differences in use of specific drugs that follows is summarized from the

World Drug Report (UNODC 2012). The *World Drug Report* is based on reports from various participating countries, so that the data can vary in quality and should be interpreted as estimates. Law enforcement information, particularly on seizures of drugs, is also used in assessing trends in international drug use. However, the *World Drug Report* is the best available information on the trends in the global use of different illicit drugs.

Cannabis

Cannabis is the most prevalent of illicit substances used globally; it is estimated that there are between 120 and 224 million users of cannabis worldwide. Cannabis cultivation has increased in recent years, although many of the increases are small-scale growing operations. While the cannabis herb is prevalent in most countries, cannabis resin, or 'hashish', is more heavily utilized in locations including Afghanistan, the Middle East, and small pockets of Western Europe and northern Africa. The highest level of cannabis use is reported in Australia and Oceania, with annual prevalence of use among adults of 9.1–14.6 per cent, followed by North America (10.8 per cent of adults), Western and Central Europe (7 per cent of adults), and West Central Africa (5.2–13.5 per cent of adults). The prevalence of cannabis use in Asia is low (1–3.4 per cent of adults), however given the very large population of the region, it remains the largest population of cannabis users worldwide.

Opioids

Opioid consumption has remained stable recently, with annual prevalence rates ranging from 0.6 per cent to 0.8 per cent among adults. The highest levels of opioid use were in North America (3.8–4.2 per cent of adults), Oceania (2.3–3.4 per cent of adults), and Eastern Europe and South Eastern Europe (1.2–1.3 per cent of adults), all of which reported higher than global average use. It is important to note that prescription opioid users outnumber heroin users in North America and Australia while in Eastern Europe and South Eastern Europe heroin is the main opioid of use. Increase in heroin use was observed in 2010 in South Asia and South East Asia as well as several African countries, while in Europe, synthetic opioids including fentanyl and buprenorphine have replaced much of the heroin use in countries such as Estonia and Finland. In Russia, as a result of a recent shortage in heroin, increases in desomorphine, acetyl opium and fentanyl have been reported.

Cocaine

Prevalence of cocaine consumption among 15–64-year-olds has remained recently relatively stable, ranging from 0.3 per cent to 0.4 per cent. While there have been slight decreases in cocaine consumption in the United States between 2006 and 2010, the same decreases were not observed in Europe, where cocaine use continues to remain stable, and in Australia, where cocaine use has seen a slight increase. Emerging trafficking routes for cocaine, especially in Africa, may have led to a spillover of use in that region.

Cocaine use is most prevalent in North America (1.6 per cent of adults), Western and Central Europe (1.3 per cent of adults), and Oceania (1.5–1.9 per cent of adults). There were decreases noted between 2009 and 2010 in North America (1.9–1.6 per cent of adults) and South America (0.9–0.7 per cent of adults), while

increases were noted in Oceania (1.4–1.7 per cent to 1.5–1.9 per cent of adults), reflecting increases in Australia specifically. While limited data exist in Africa and parts of Asia, there are indications that there is an increasing and emerging use of cocaine in those regions; this may reflect the increased trafficking of cocaine through these areas.

Amphetamine-type stimulants

The illicit use of ATS, which includes methamphetamine, ecstasy, and amphetamine, is more difficult to measure globally due to the small-scale operations that are used to produce these illicit drugs, but has been estimated to be between 0.3 and 1.2 per cent of the global population. Based on seizures of amphetamine, use has decreased in recent years and has been surpassed by methamphetamine use. Seizures of ecstasy have increased in recent years, especially in the European market, doubling from 2009 to 2010; the availability of this drug has also increased in other regions including the United States, South East Asia, and Oceania. New trade routes that often are used for cocaine trafficking are increasingly being used for ATS trafficking, with evidence of spillover into West Africa.

ATS (excluding ecstasy) is most prevalent in Oceania, North America, and Central America, while there is evidence of increasing use in Asia, especially with the increased seizure of methamphetamine in the region. Ecstasy use globally is comparable to prevalence rates of cocaine use (0.2–0.6 per cent of the population aged 15–64), but higher rates were observed in regions including Oceania (2.9 per cent of population aged 15–64), North America (0.9 per cent of population aged 15–64), and Western and Central Europe (0.8 per cent of population aged 15–64). Ecstasy in particular tends to be much more prevalent in young people; of the estimated 2.6 million users in 2010 in the United States, 2.5 million were between the ages of 15 and 34, while in Europe, of the estimated 2.5 million users in 2010, 2 million were between 15 and 34 years of age. As a whole, this group of drugs remains the second most used drug globally (behind cannabis).

Historical interpretation and implications for public health

Even with the imprecision in the global data, there are identifiable patterns in drug use in different regions of the world. Some of these patterns reflect cultural differences, as the illicit use of different drugs has been incorporated to varying degrees into different cultures and different national societies. The primary factor in the geographical distribution of the use of different drugs, however, involves production, distribution networks and markets. Various drugs are produced in specific geographic areas and then transported through complex networks to established markets. Once production has become established in a geographic area and once a market for a drug has been established in an area, it is very difficult to fundamentally change these factors. The reinforcing nature of drug use leads many persons to continue using drugs and often paying very high prices for the drugs. (At least very high prices compared to the costs of producing the drugs.) Once production capabilities have become established in a geographic area, it can be quite difficult to dislodge them. The production usually becomes integrated into the local culture, including corruption of local authorities.

This is not to say that drug production areas, distribution routes, and drug markets cannot change. Two types of changes are of particular relevance to public health. First, over the last several decades globalization has transformed the illicit drug business just as it has transformed licit businesses. The improvements and cost reductions in communication, transportation, and the ability to transfer capital, have greatly increased the diffusion of illicit drug use to many new countries.

Second, while law enforcement efforts have generally not been able to stop international drug distribution, law enforcement efforts have led to rerouting of distribution routes. As a result local drug markets and drug problems typically develop along the new distribution routes. For example, new routes and new drug problems have developed most recently in Africa (UNODC 2012).

The implications of these changes in drug production, distribution, and marketing for public health are both clear and of considerable concern. Illicit drug use is likely to continue in areas where it is currently established and is likely to diffuse to new areas. Public health officials need to plan for continued—and perhaps increased—use of illicit drugs and implement programmes to reduce the health and social problems associated with illicit drug use.

Epidemiological methods for studying illicit drug use

As illicit drug use is, by definition, illegal there are many difficulties in collecting rigorous data on the topic. The difficulties include: (1) social desirability responding (Pauls and Stemmler 2003) in which persons who use drugs may deny (or minimize) their drug use in order to present a desirable image to the researchers and/or to themselves; (2) locating subjects, as many persons who use drugs at high levels may be homeless or unstably housed; and (3) the effects of drugs on memory (though greatest memory problems may be associated with alcohol use). Various techniques have been developed to reduce these problems including: (1) audio-computer assisted self-interviewing (ACASI) (Des Jarlais et al. 1999), in which questionnaires are programmed into computers so that the research subject listens to the questions over headphones and responds to the questions using either the keyboard or a touch screen. ASCSI does not require the subjects to be literate and the questions can be presented identically to all subjects; (2) respondent-driven sampling (Heckathorn 1997), in which subjects are reimbursed for recruiting other subjects. Restrictions are placed on the numbers of subjects that any individual subject can recruit, and additional data is collected in order to increase generalizability to the underlying population; and (3) timeline follow back (Sobell and Sobell 1992), a method in which major events in a subject's life are used to anchor to the recall of events over long time periods.

There are several major methods for studying the epidemiology of illicit drug use. These include household surveys of the general population, school surveys of drug abuse among young adults, administrative data from the Treatment Episode Data Set, and special studies aimed at examining drug use among particular groups, such as those who use drugs at high frequencies.

Household surveys of the general population

Surveys of random samples of household members provide what is usually considered to be the best estimates of the use of different

drugs in a country. Such surveys are quite expensive but provide data that cannot be obtained through any other method. The US National Survey of Drug Use and Health (Substance Abuse & Mental Health Services Administration 2012) is conducted annually with a sample of over 67,500 respondents age 12 years or older. The findings from the most recent year (2011) indicate that 9.4 per cent reported any illicit drug use in the previous year, and 8.7 per cent reported illicit drug use in the previous month. The most commonly used illicit drug was marijuana, with psychotherapeutics the second most commonly used illicit drug. Additionally, there were an estimated 1.9 million people with non-medical use of pain relievers in 2011; this figure remained unchanged from 2010.

School surveys

Surveys can also be conducted in schools. School-age youth are of particular interest because illicit drug use typically begins during adolescence, and trends in the use of different drugs are often much more pronounced in this age group. Thus, school surveys may be particularly useful for generating predictions about future drug use. 'Monitoring the Future' is the largest and longest running school survey in the United States (Johnston et al. 2011). In the 2011 survey, of the 46,700 students who were interviewed, 34.7 per cent of US high school students reported using illicit drugs in the previous year, with marijuana, used by 31 per cent, being the most commonly used illicit drug and inhalants being the second most commonly used illicit drug.

Administrative data

Persons with SUDs frequently come into contact with both law enforcement and health agencies. They may be arrested for possession of drugs and/or they may seek treatment for both their substance abuse disorder and for related health problems, such as overdose and infections. According to the Treatment Episode Data Set (TEDS) (Department of Health and Human Services 2008), there were 1.8 million admissions to licensed drug and alcohol treatment programmes in 2007, a slight decrease from the nearly 1.9 million admissions in 2006. Among those seeking treatment, five substances accounted for 96 per cent of TEDS admissions: alcohol (40 per cent), opiates (19 per cent, primarily heroin), marijuana/hashish (16 per cent), cocaine (13 per cent), and stimulants (8 per cent, primarily methamphetamine). The number of admissions for these five illicit substances decreased slightly from 2006 to 2007.

Special studies

While surveys can provide data about the breadth of drug use in the general and school populations, and administrative data can provide useful information about problems associated with illicit drug use, these types of studies do not provide the depth of information needed to understand the problems associated with specific forms of illicit drug use. Special studies usually recruit persons who use drugs at high frequencies. Injecting drug users with or at risk for HIV infection are an example. Special studies may also recruit subjects from clinical (drug treatment programme) settings from the community. They may be cross-sectional (one-time data collection) or cohort studies (with the same subjects followed over time).

Public health consequences of drug use

There are many different adverse consequences of drug use, both for individuals, their families, and for society as a whole. These

include the disruption of psychological and social functioning due to drug use itself, the spread of infectious diseases associated with drug use, particularly injecting drug use, and drug-induced fatal overdoses.

Dependence/addiction/disorder

Differentiation between substance use and substance use disorders

In theory, individuals can use psychoactive substances without experiencing problems, symptoms, or impairments from the substances. In the case of alcohol, light or moderate use is associated with a number of health benefits (e.g. decreased cardiovascular mortality) compared to abstainers, in what has been called the 'J-shaped curve' (Costanzo et al. 2010). However, progression from non-problem to problem use appears to be much more likely for illegal psychoactive substances, particularly cocaine and opioids (Lev-Ran et al. 2013). Clinical and research experts distinguish between substance use and problem SUDs through the diagnostic criteria for SUDs. These are most often assessed through the criteria provided to the mental health and substance abuse fields in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association. The first two editions of the DSM did not include specific criteria, but based on research conducted in the 1970s, such criteria were first presented in the third edition, DSM-III (American Psychiatric Association 1980), in 1980. The criteria for SUDs have undergone considerable evolution since this first presentation.

DSM-III

DSM-III was the first to divide SUDs into abuse and dependence. Abuse (pathological use, consequences, e.g. impaired functioning) was considered to be the milder condition (Rounsaville et al. 1986), while dependence, characterized by physiological components (i.e. tolerance and/or withdrawal), was assumed to be more severe. However, a rationale for the actual selection and organization of the criteria was never published. The approach was criticized and a better approach sought (Rounsaville et al. 1986).

The Dependence Syndrome

Developed separately from DSM-III, the 'Dependence Syndrome' (Edwards and Gross 1976; Edwards et al. 1981) posited a 'bi-axial' SUD concept (Edwards and Gross 1976; Edwards et al. 1981): (1) broader *dependence* concept (inability to control use, indicated by tolerance, withdrawal, other criteria), and (2) *consequences* of use (social, legal, medical).

DSM-III-R, ICD-10, and DSM-IV

The Dependence Syndrome was the basis of the definition of dependence in DSM-III-R (Rounsaville et al. 1986), published in 1987, the 10th edition of the International Classification of Diseases (ICD-10) published in 1992, and DSM-IV, published in 1994. Initially, only dependence was proposed for DSM-III-R (Rounsaville et al. 1986), but concerns that lack of a secondary diagnosis would leave individuals without treatment led to the addition of abuse (Hasin et al. 2013). The initial presentation of the Dependence Syndrome included an assumption that dependence and its consequences were related, but DSM-III-R and DSM-IV

defined abuse hierarchically to dependence, that is, abuse was not to be diagnosed if dependence was present (Hasin et al. 2006a).

DSM-IV dependence: valid, reliable

The seven criteria for DSM-IV dependence include: (1) withdrawal, (2) tolerance, (3) using in larger amounts or for longer periods than intended, (4) repeated efforts to stop or control use, (5) much time spent using, (6) physical or psychological problems related to use, and (7) important activities given up in order to use. DSM-IV dependence is diagnosed if at least three criteria are present within a 12-month period. A review (Hasin et al. 2006a) from one of the NIH planning conferences showed that DSM-IV substance dependence, diagnosed with three or more criteria, was highly reliable in a number of test-retest studies in varied populations, as were continuous measures of the dependence criteria. DSM-IV dependence also showed strong validity in cross-sectional and prospective US and international studies. Consequently, dependence has been the diagnosis routinely used as an inclusion criterion in trials of pharmacological interventions, is often studied in controlled experiments oriented to treatment development, and is a common phenotype in molecular genetic studies.

DSM-IV abuse: a category with many problems

The four criteria for DSM-IV abuse include: (1) hazardous use, (2) social or interpersonal problems related to use, (3) neglect of major roles in order to use, and (4) legal problems related to use. DSM-IV abuse is diagnosed only in the absence of dependence. Abuse is diagnosed if one or more of the criteria are present. A number of problems were identified with DSM-IV *abuse* and its hierarchical relationship to dependence. (1) *Lack of a justifiable concept*. Abuse diagnosed with one criterion may be normative in some groups, for example, driving after drinking. While this is risky behaviour, it is arguably not sufficient grounds for a psychiatric diagnosis. (2) *Inconsistent reliability*. The test-retest reliability of abuse is often much lower than dependence (Hasin et al. 2006a). (3) *Validity of assumptions about abuse and dependence*. Researchers and clinicians alike have assumed that abuse is the mild diagnosis and dependence is more severe. This has led to several incorrect assumptions about their relationship that are not supported by empirical findings. For example, abuse is not necessarily a prodromal stage of dependence (Hasin et al. 1990, 1997; Schuckit et al. 2000; Grant et al. 2001; Schuckit and Smith 2001). In addition, not all dependence cases have abuse criteria (Hasin et al. 1990, 1997, 2005; Schuckit et al. 2000; Grant et al. 2001, 2007; Schuckit and Smith 2001; Hasin and Grant 2004). Further (as is apparent on inspection of the face validity of the criteria), the criteria defining abuse are not all mild relative to dependence.

Diagnostic 'orphans'

Undiagnosed 'orphans' with two dependence and no abuse criteria may be more serious than single-criterion abuse cases (Hasin and Paykin 1998; Pollock and Martin 1999).

DSM-5

DSM-5 was published in May 2013. Changes in DSM are intended to implement new knowledge, improve validity, reduce clinician burden, and correct problems identified in previous versions. In 2007, the American Psychiatric Association convened the

Substance Disorders Workgroup to identify DSM-IV strengths and weaknesses and recommend improvements. Correcting problems with DSM-IV abuse was a major issue faced by the Workgroup (Schuckit and Saunders 2006; Hasin et al. 2013). Other issues included adding or dropping criteria, and setting a diagnostic threshold.

Relationship of DSM-IV abuse and dependence

Factor analyses of dependence and abuse criteria showed either a single factor or two factors whose high correlations often led to interpretation that a single dimension was warranted (Hasin et al. 2006a; Hasin et al. 2013). Item response theory (IRT) was a method used by workgroup members and other investigators to provide more information about the relationship of criteria to each other than factor analytic studies. Results from 39 IRT studies with over 200,000 subjects (e.g. Hasin et al. 2013) had two very consistent findings. First, DSM-IV dependence and abuse criteria (except legal problems) were always *unidimensional*, indicating a single condition (Hasin et al. 2013). Second, abuse and dependence criteria were always *intermixed across the severity spectrum* (Hasin et al. 2013), indicating that abuse criteria are not necessarily milder than dependence. These findings supported adding abuse to dependence to create a single DSM-5 SUD, solving some of the problems with abuse.

Specific criteria

The Workgroup focused on legal problems (abuse) and craving. Reasons to drop *legal problems* included low prevalence, little added information, poor discrimination and fit with other criteria (Hasin et al. 2013). In secondary analysis of clinical data (Hasin et al. 2012), no patient 'lost' a diagnosis without this criterion. Addition of *craving* was suggested by behavioural and biological studies (O'Brien et al. 1998; Miller and Goldsmith 2001; Waters et al. 2004; O'Brien 2005; Weiss 2005; Foroud et al. 2007; Heinz et al. 2009). IRT shows that craving is unidimensional with the other criteria, but may be redundant (Mewton et al. 2011; Casey et al. 2012). Results comparing IRT total information curves for SUD criteria with and without craving were inconsistent. Some though not all consider craving to be central to diagnosis and treatment (Hasin et al. 2013).

Workgroup recommendation: DSM-5 SUD

DSM-IV dependence was reliable and valid. An enormous amount of evidence indicated that dependence and three of the abuse criteria were indicators of the same single underlying condition, with available evidence showing that craving also fit within this latent trait. Therefore, the Workgroup recommended adding the abuse criteria and craving to dependence to define a single DSM-5 SUD (Hasin et al. 2013). These recommendations were implemented as the new DSM-5 SUD (Hasin et al. 2013).

Threshold

In inherently dimensional conditions such as SUD, identifying a threshold for multiple purposes (e.g. treatment; research) is challenging (Kendler and Gardner 1998; Hasin et al. 2006b, 2013). In the absence of a strong empirical basis for defining a diagnostic threshold (i.e. minimum number of criteria necessary to make a diagnosis), the Workgroup sought a threshold maximizing

agreement with the prevalence and with DSM-IV abuse or dependence to avoid unduly affecting prevalence rates. In secondary analyses of existing epidemiological and clinical data (Hasin et al. 2012; Peer et al. 2013), two or more criteria accomplished this (Hasin et al. 2013).

Severity levels

All DSM-5 workgroups were asked to create mild, moderate, and severe severity indicators. The Workgroup preferred a simple unweighted criterion count as evidence-based (Hasin et al. 2006b, 2013; Hasin and Beseler 2009; Beseler and Hasin 2010; Dawson et al. 2010), but busy clinicians find rating dimensions 'burdensome' (Frances 2009). Therefore, the Workgroup defined mild, moderate and severe as two to three, four to five, and six or more SUD criteria, respectively.

Name of the DSM-5 disorder and chapter

Each version of DSM includes a chapter on substance-related conditions that defines not only the disorders just discussed, but also such conditions as substance-specific intoxication and withdrawal syndromes, and substance-related mental disorders (e.g. substance-induced mood disorder). For DSM-5, the Workgroup was asked by the American Psychiatric Association Board of Trustees to accept Gambling Disorder as a related disorder in the chapter. To accommodate this change, a change in the title was necessary. The Board of Trustees assigned the title, 'Substance-Related and Addictive Disorders', despite the DSM-5 SUD Workgroup having previously approved a title (by majority but not consensus) not including the term 'addiction'. This lack of agreement over the title reflects an overall tension in the field over the terms 'addiction' and 'dependence', as seen in editorials (O'Brien et al. 2006; O'Brien 2011) advocating 'addiction' as a general term, reserving 'dependence' specifically for tolerance and/or withdrawal, and the more than 80 comments on these editorials that debated the pros and cons of these terms. Issues with the terms 'dependence' and 'addiction' involve the stigma associated with each, and with assumed confusion on the part of general medical practitioners about whether dependence involves only tolerance and withdrawal, or indicates a wider phenomenon. Resolving these issues empirically appears difficult, and therefore some continued debate appears likely. However, the term 'substance use disorder' avoids this debate and can be used generally.

Future directions

The logic underlying the changes made to DSM-5 SUD was based on extensive evidence that DSM-IV dependence was valid and that the eleven criteria defining DSM-5 SUD were all indicators of the same underlying trait. Therefore, the Workgroup reasoned that the condition defined by the eleven criteria would also be valid. However, collecting and analysing empirical data supporting this reasoning was beyond the mandate of the Workgroup, and beyond the time and resources available for its work. (Similar conditions limited DSM-IV SUD validity studies prior to the publication of DSM-IV in 1994, leaving issues for subsequent research.) The combination of abuse and dependence into a single disorder solves many of the problems that were identified with abuse in DSM-IV. After the publication of DSM-5 in 2013, studies of the antecedent, concurrent, and predictive validity of DSM-5 SUD compared

to DSM-IV dependence would provide needed information about additional benefits of the changed criteria for SUDs in DSM-5.

Infectious diseases

Infectious diseases have become one of the most important adverse consequences of illicit drug use. This is particularly true for the injection of illicit drugs, as the multiperson use (sharing) of the needles and syringes for injecting is a relatively efficient method for transmitting blood-borne viruses. Drug use can also affect sexual behaviour—drug users may exchange sex for drugs or money to purchase drugs, sexual decision-making may be impaired under the influence of drugs, and some drugs may increase the perceived pleasure of sex, leading to more frequent or prolonged sexual activities. Thus, drug users often have elevated rates of sexually transmitted infections compared to demographically similar persons who do not use drugs (Zenilman and Shahmanesh 2011). Of course, high rates of drug use can also impair sexual functioning or reduce sexual desire (Smith 2007), leading to lower rates of sexual activity among drug users.

HIV/AIDS

HIV/AIDS has been an extremely dramatic development in the field of psychoactive drug use. The use of psychoactive drugs (both licit and illicit) always carried some risk of death, but HIV/AIDS increased the risk of death by several orders of magnitude. AIDS was first observed among persons who inject drugs in 1981 (Centers for Disease Control and Prevention 1981), and the development of the HIV antibody test provided good information on the size of the problem, and confirmed that sharing needles and syringes was the dominant mode of HIV transmission among persons who injected drugs (PWID) (see Chapter 8.13).

The initial studies in cities such as New York showed approximately half of the drug injectors in the city were infected with the virus (Des Jarlais et al. 1989). It also rapidly became clear that the virus could be transmitted to newborn children and to non-drug injecting sexual partners (Padian et al. 1987; Barzilai et al. 1990; Morgan et al. 1990; Kane 1991; Moschese et al. 1991). At the time, there was no effective treatment for HIV infection, and AIDS was almost uniformly fatal. AIDS thus suddenly became a severe threat to the lives of very large numbers of PWID, their sexual partners and their newborn children. The emergence of this new threat to the lives of drug users and their communities generated a great deal of public attention. In some areas, such as the Netherlands (Buning et al. 1988), the United Kingdom (Stimson et al. 1988), and Australia (Lowe et al. 1990), this led to rapid pilot testing and implementation of effective programmes for reducing HIV transmission. In other areas, the stigmatization of drug users and the fear of doing anything that might ‘condone’ or ‘encourage’ drug use, prevented implementation of effective prevention programmes (Anderson 1991). As noted later, this political will problem continues to this day.

Another disturbing factor that emerged from the early research on HIV among PWID was the potential for extremely rapid transmission of the virus among some groups of drug users. HIV can spread very rapidly among PWID, with increases in HIV prevalence from 10 per cent to 50 per cent per year (Des Jarlais et al. 2012). The city of Bangkok, Thailand, experienced a well-documented example of extremely rapid transmission,

with HIV prevalence increasing by approximately 4 per cent per month during a period in 1989 (Vanichseni and Sakuntanaga 1990). There appear to be several factors that facilitate situations of very rapid transmission (Nyindo 2005), including: (1) the local population of drug injectors is not aware of the threat of HIV/AIDS and thus do not reduce their risk behaviour, (2) effective restrictions on access to sterile needles and syringes, and (3) mechanisms that generate rapid injecting partner change, in which drug users may share needles and syringes with large numbers of other drug users over a short time period. These mechanisms include shooting galleries, where drug users come to rent needles and syringes, return the used equipment to the persons operating the gallery, who then rent the used needle and syringe to other drug users; ‘dealer’s works’, where a person selling drugs may have a needle and syringe to lend to customers, who use and then return the needle and syringe for use by the next customer, ‘hit doctors’, who for a small fee will inject drug users who have difficulties injecting themselves, and the same needle and syringe may be used for many of the hit doctors’ customers; and semi-public injecting sites such as abandoned buildings where large numbers often congregate to inject with a very limited number of needles and syringes. Homeless drug users are particularly likely to use such semi-public injecting sites.

HIV is highly infectious during the acute infection stage (Brenner et al. 2007) so that these mechanisms that generate sharing needles and syringes among large groups of injectors may be a critical component of very rapid transmission of HIV. The mechanisms may also develop rather quickly, with changes in law enforcement activities, drug distribution patterns, the frequencies of drug injection, and the economic circumstances in the local population of PWID. A situation in which HIV does not appear to be a threat among PWID can rapidly change to a situation in which a high seroprevalence epidemic has already occurred.

While there are clear difficulties in monitoring the evolving situation with respect to HIV among PWID, injecting drug use and HIV infection among PWID continues to spread globally. In 2004 there were 130 countries with injecting drug use and 78 countries with HIV among PWID (Aceijas et al. 2004). In 2008 there were 148 countries with injecting drug use and 120 countries with HIV among PWID (Mathers et al. 2008). The study in *The Lancet* (Mathers et al. 2008) shows HIV prevalence in different countries throughout the world. There are five countries where HIV prevalence has exceeded 20 per cent and nine countries where HIV prevalence has exceeded 40 per cent. The same factors that have led to great increases in global trade overall—improvements in transportation, communication, fewer restrictions on the flow of capital—have also led to increased trade in illicit drugs. Given these factors and the tremendous profits to be made in the distribution of illicit drugs, there would not appear to be any immediate likelihood of reducing the illicit supply of psychoactive drugs. We will therefore need to continually address the many health problems associated with the injection of psychoactive drugs.

In stark contrast to the potential for extremely rapid transmission of HIV among PWID discussed earlier, it is also well established that it is possible to avert HIV epidemics among PWID. Large-scale implementation of HIV prevention programmes, particularly needle/syringe access programmes, when HIV prevalence is very low in a population of PWID can keep the prevalence low (under 5 per cent) indefinitely (Des Jarlais et al. 1995;

Stimson 1995; Wodak and Maher 2010; Iverson et al. 2012). It is important to note, however, that there have been instances of outbreaks of HIV when it appeared that HIV was under control in the local PWID population. The most famous of these is probably the Vancouver outbreak (Strathdee et al. 1997), and the most recent outbreak of HIV among PWID that occurred in Greece (Paraskevis et al. 2011).

One important aspect of successful HIV prevention in many countries has been the active involvement of drug users and former drug users themselves (Kerr et al. 2006). They have often served as front line, community outreach prevention workers and have formed user groups and networks to represent their interests in policy decision-making. The contributions of these groups have often been critical for the on-the-ground effectiveness of HIV prevention programmes (Wood et al. 2003).

The above examples of highly successful HIV prevention programming are all from high-income countries. Most—but certainly not all—of current HIV transmission is occurring in low- and middle-income countries (Mathers et al. 2008) and we do not yet have sufficient long-term data from HIV prevention programming in resource-limited settings to draw any firm conclusions with respect to effectiveness. There are multiple reasons for the lack of long-term data on the effectiveness of HIV prevention for PWID in low- and middle-income countries: HIV epidemics among PWID in low- and middle-income countries generally occurred more recently than HIV epidemics among PWID in high-income countries, implementation of HIV prevention in low- and middle-income countries is generally at very low levels (Mathers et al. 2010), and there have often been insufficient resources for conducting long-term outcome studies.

There are several concerns for why prevention programming may not be as effective in low- and middle-income countries as in high-income countries. First, there is the simple scarcity of resources for prevention programmes. Some types of HIV prevention programmes, particularly long-term drug treatment programmes and antiretroviral treatment for HIV, are comparatively expensive, and it may not be possible to provide these on a public health scale in many low- and middle-income countries. This is not simply a matter of financial resources, but also a matter of appropriately trained health workers.

Second, while PWID are stigmatized in almost all countries, the stigmatization may be particularly severe in many low- and middle-income countries. This may lead political leaders to be less willing to allocate resources to HIV prevention and treatment for PWID. In particular, to the extent that injecting drug use is seen as a practice associated with degenerate Western culture, nationalism in low- and middle-income countries may lead political leaders to fail to implement evidence-based HIV prevention programmes for PWID (Rhodes et al. 2003; Cohen 2010). The stigmatization of injecting drugs may compound the stigmatization of having (or simply being at risk for) HIV, leading PWID to avoid using the programmes that are available.

Third, effective HIV prevention programmes require at least passive cooperation from law enforcement, and relationships between drug users and law enforcement may be particularly problematic in many low- and middle-income countries. In some countries, drug addiction may be a status offence (simply being an addict is sufficient basis for incarceration, without having to be found in possession of drugs). Many low- and middle-income

countries also have official registries of persons known to be addicted, and persons on these registries may lose important civil rights. Addicts may also be subject to police brutality (Booth et al. 2003; Wolfe et al. 2010). Thus, drug users may be very reluctant to participate in HIV prevention activities if such participation risks exposure to law enforcement activities. Carrying clean needles and syringes, in particular, may be risky for drug users in such settings.

Fourth, and of critical importance, political leaders in some transitional, low- and middle-income countries have viewed injecting drug use as a foreign, ‘decadent’ behaviour from the West that must be resisted in order to protect cultural traditions. Thus, interventions that appear to accept continuing drug use (such as syringe exchange) or appear to merely substitute the use of one narcotic drug for another (methadone maintenance treatment) are strongly resisted regardless of scientific evidence. One of the most important examples of this cultural resistance is the Russian opposition to methadone maintenance treatment (Wolfe 2007; Burki 2012).

Sexual transmission of HIV among drug users

As noted earlier, HIV is transmitted among drug users not only through the sharing of injecting equipment but also sexually. Both injecting and non-injecting drug use may facilitate sexual transmission of HIV through multiple mechanisms, including: exchange of sex for drugs or money to obtain drugs, impaired decision-making regarding safer sex (use of condoms, restricting the number of partners) when under the influence of drugs, and, for some drugs, perceived increases in sexual pleasure when combining drug use with sexual activity.

There have been a number of interventions developed to reduce unsafe sexual activity among injecting and non-injecting drug users (Meader et al. 2013). These interventions typically provide information about sexual transmission of HIV, the effectiveness of condoms in reducing sexual transmission, and may include skills training in topics such as correct condom use and negotiating safer sex. These interventions do have evidence of efficacy in changing sexual behaviour, but with only modest effect sizes. Thus, the most effective method of reducing sexual transmission of HIV among PWID may be to avert epidemics of injecting-related transmission in the first place.

Since the mid-1990s, various types of antiretroviral treatment (ART) medications have been developed to treat HIV infection. When used in combination, these medications can arrest the damaging effects of HIV on the immune system and restore health. Combination ART does not cure HIV infection but can significantly reduce viral loads among persons with the infection and is literally life-saving. Drug users, however, have generally benefited less than others from these medications. Drug users are often diagnosed late with HIV and have higher mortality rates from the virus (Grigoryan et al. 2009). Adherence to ART regimens can be difficult for many patients, but particularly for persons who are actively using drugs. With appropriate support services, however, drug users do as well as others on ART (Wisaksana et al. 2010).

The discovery of HIV/AIDS among persons who inject drugs forced a re-examination of public policies towards drug use. AIDS greatly increased mortality among persons who inject and the virus was transmitted to non-injecting sexual partners and newborn children. The activist and scientific responses have been

impressive. We now have a consensus on the elements of 'comprehensive prevention, care and treatment of HIV' for persons who inject drugs (World Health Organization (WHO) 2009), including needle and syringe programmes, opiate substitution treatment, HIV testing and counselling, ART, prevention and treatment of sexually transmitted infections, condom programmes for PWID and their sexual partners, targeted information, education and communication for PWID and their sexual partners, and vaccination, diagnosis, and treatment of viral hepatitis infection. Implementation of these components at sufficient scale can avert HIV epidemics and reverse epidemics that have developed. However, implementation is inadequate in many countries (Mathers et al. 2010). Whether adequate implementation will occur is partially a matter of scarce resources, but primarily a matter of the stigmatization of drug users and the lack of political will to commit resources to the problem (Des Jarlais et al. 2010).

HCV among persons who inject drugs

Both HIV and hepatitis C virus (HCV) are transmitted through sharing of drug injection equipment. HIV co-infection increases HCV disease progression, and the great majority of HIV seropositive PWID are also infected with HCV.

HCV is much more transmissible through shared injection equipment than HIV, and can be effectively transmitted through the sharing of drug preparation equipment (cookers, filters) (Hagan et al. 2001), so that HCV prevalence is usually much higher than HIV prevalence among PWID. A recent systematic review found reports on HCV antibody prevalence in PWID in 77 countries (Nelson et al. 2011). Using midpoint estimates, country-specific prevalence ranged from 10 to 90 per cent, although in 25 countries prevalence was between 60 and 80 per cent, and in 12 it exceeded 80 per cent. The total number of anti-HCV positive PWID worldwide was estimated to be 10 million. A systematic review and meta-regression of time to acquisition of HCV infection in PWID also showed that, in high-income countries, HCV prevalence declined after 1995, corresponding to a period when harm reduction services expanded in these regions of the world (Hagan et al. 2008). Other recent studies have shown that combination prevention strategies—substance use treatment and access to sterile injecting equipment—are also associated with reduced likelihood of HCV seroconversion at the individual level (Hagan et al. 2011; Turner et al. 2011). However, there are currently no areas, even in high-income countries, where combined prevention has limited HCV incidence among PWID to less than 1/100 person-years at risk, as has been achieved by combined prevention for HIV among PWID.

Treatment of chronic HCV infection benefits individual patients and will also remove a source of infectiousness in the local PWID population. When treated with the new direct-acting antivirals (Food and Drug Administration 2012), up to 75 per cent of patients with genotype 1 infection may achieve a sustained virological response (SVR), in comparison to 40 per cent SVR in those treated with the previous regimen of pegylated interferon and ribavirin (Manns et al. 2001; Fried 2002; McHutchison et al. 2009; Kwo et al. 2010). (SVR involves eradication of the HCV in the body. It can be considered a cure, and lifelong treatment is *not* required in contrast to antiretroviral treatment for HIV.) Interferon can cause relatively severe side effects, including depression, so that new treatment regimens that do not require interferon could greatly

increase the numbers of persons who would seek treatment and successfully complete treatment for HCV infection. Clinical trials of such new treatment regimens are currently underway.

Access to HCV treatment is currently extremely limited, and it is estimated that fewer than 5 per cent of HCV-infected PWID in the United States and Australia receive HCV treatment (Stoove et al. 2005; Paterson et al. 2007). New programmes to encourage PWID to enter treatment and provide support during treatment are also needed. Concurrent treatment for SUDs does improve completion rates for HCV treatment (Dimova et al. 2013).

Drug-induced (overdose) deaths

Drug-induced deaths (from drug overdoses) are another major adverse consequence of drug use. Narcotics are the most frequent cause of fatal overdoses because of their ability to depress respiration, but many fatal overdoses involve combinations of narcotics and other drugs such as alcohol or benzodiazepines. Data on fatal overdoses are typically obtained from toxicology studies conducted by medical examiners. Stimulant drugs such as cocaine can also induce deaths, usually by interfering with the functioning of the heart, but such cases are much less common than narcotic induced respiratory depression.

Interpreting overdose statistics as a measure of a country's drug problem can be quite difficult, as the number of recorded overdoses can depend upon a wide variety of factors including drug use patterns, injecting versus non-injecting routes of drug administration, the availability of emergency health services (and drug users' trust in calling for emergency assistance), as well as the quality of data collection and reporting.

Nevertheless, there is great variation in the numbers of fatal overdoses per capita across different countries, and these data undoubtedly reflect an important aspect of the drug problem in each country. Fig. 9.2.1 shows the reported per capita drug-induced deaths for the European Union (EU) countries for 2011.

The EU average was 21 fatal overdoses per million in the population and this has been stable for several years, but with a wide range; from under 5 per million in Romania to almost 150 per million in Estonia (European Monitoring Centre for Drugs and Drug Addiction 2011). The reasons for this great variation are not well understood, but there are undoubtedly multiple causal factors.

In the United States, drug overdose deaths have increased steadily over the last decade, primarily due to overdoses from pharmaceutical analgesics and not 'street' drugs such as heroin. In 2010, of the 38,329 overdose deaths in the United States, there were an estimated 16,651 overdose deaths due to opioid analgesics; over 75 per cent of these overdose deaths were unintentional. Opioids were also frequently implicated in overdose deaths involving other pharmaceutical drugs including benzodiazepines (77.2 per cent), antiepileptic and antiparkinsonism drugs (65.5 per cent), antipsychotic and neuroleptic drugs (58 per cent), antidepressants (57.6 per cent), other analgesics, antipyretics, and antirheumatics (56.5 per cent), and other psychotropic drugs (64.2 per cent). These data highlight the frequent involvement of drugs to treat mental health disorders in overdose deaths, such as benzodiazepines, antidepressants, and antipsychotics (Jones et al. 2013).

Reducing the numbers of persons using opioid drugs through effective substance use treatment would reduce the chances of

Fig. 9.2.1 European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) 2011 estimated mortality rates among all adults (15–64 years) due to drug-induced deaths.

Reproduced from European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), Drug-related infectious diseases and drug-related deaths, in EMCDDA (ed.), *Annual Report 2011: The State of the Drugs Problem in Europe*, Publications Office of the European Union, Luxembourg, Copyright © 2011.

overdose deaths. This can be a slow process, however, and the period just after a person has left treatment can be a high-risk period for overdose. The person will have lost tolerance so that his or her usual dose may precipitate an overdose. There are also methods for reducing overdose deaths without reducing drug use itself. Many syringe exchange programmes distribute naloxone to their participants and have trained participants in how to administer naloxone to a fellow user experiencing an overdose (Guardino et al. 2010). Naloxone is a very potent narcotic antagonist and can reverse an overdose within minutes. The US state of North Carolina has implemented a naloxone distribution programme specifically designed to provide naloxone for reversing pharmaceutical analgesic overdoses (Centers for Disease Control and Prevention 2012).

Treatment of substance use disorders

While there are effective methods for reducing transmission of infectious pathogens and for reducing overdoses among persons who use drugs, the ideal method for addressing these problems would be to eliminate drug use among persons with SUDs. We are very far from having treatments that produce permanent abstinence among persons with SUDs. Indeed, SUDs are best considered as ‘chronic, relapsing conditions’, for which treatment may reduce drug use but that return to drug use should be expected for the great majority of those who receive treatment.

The WHO, UNODC, and the Joint United Nations Programme on HIV/AIDS (UNAIDS) technical guide outlines a comprehensive package for prevention and treatment for PWID (WHO et al. 2012). Included in this package are needle and syringe

programmes, opiate substitution treatment (OST), HIV testing and counselling, antiretroviral treatment, prevention and treatment of sexually transmitted infections, condom programmes for PWID and their sexual partners, targeted information, education, and communication for PWID and their sexual partners, prevention, vaccination and treatment of viral hepatitis, and prevention, diagnosis, and treatment of tuberculosis. This comprehensive package has been endorsed by the WHO, UNAIDS, UNODS, the UN General Assembly, the Economic and Social Council, the UN Commission on Narcotic Drugs, the Global Fund, and PEPFAR (WHO et al. 2012). According to their guidelines, a ‘moderate’ level coverage for these services should include at least 100 to 200 syringes per PWID per NSP, at least 20–40 per cent of PWID in opiate substitution treatment, and 25–75 per cent of PWID who are HIV positive receiving ART medication.

Opiate substitution treatment/medication assisted treatment

OST has been implemented for nearly 50 years, and has gained wider acceptance, especially among developing countries, in the last 5–10 years. Opiate use continues to be problematic globally, with an estimated 12.8–21.9 million people using heroin, or illicit opiates, in the last 12 months (UNODC 2012); nearly 50 per cent of these users are in Asia (Mathers et al. 2008).

There are two primary types of pharmacological medication used to treat opiate use: methadone, which has been used for decades, and more recently, buprenorphine. These two substances are approved as essential medicines for treatment of opiate abuse by the WHO (Farrell et al. 2012).

Public and private clinics throughout the world manage opiate addiction with opiate substitution therapy, and the results of these programmes over the years have generally been quite positive. Studies evaluating OST programmes have shown very substantial reductions in both drug use, and the associated risk behaviours associated with opiate use such as drug injection and sharing of injection-related equipment (Gowing et al. 2011). Additionally, measurements examining the quality of life of drug users in OST programmes have shown positive changes in drug users' lives, with more positive changes seen the longer patients remain in treatment (Padaiga et al. 2007; Lua and Talib 2012; Wang et al. 2012).

A review completed in 2013 among low- and middle-income countries examined the overall success of retention among participants in OST programmes. A total of 58 studies from 12 different countries were included, and overall retention was above 50 per cent after 12 months, and retention values were similar to studies conducted in high-income countries (Feelemyer 2014).

As many behaviours associated with opiate use, including drug injection, are associated with blood-borne infections such as hepatitis C and HIV, OST programmes act not only as a means to reduce drug use, but also to reduce the transmission of disease among PWID and their sexual partners (Mark et al. 2006).

Cognitive behavioural therapy

Cognitive behavioural therapy (CBT) is used in many clinical settings to treat symptoms of addiction, neurosis, and personality disorders. Applied in Marlatt and Gordon's model of relapse prevention (Marlatt and Donovan 2005), CBT for drug addiction targets cognitive, affective, and situation triggers for substance use while at the same time providing necessary skills and training needed for coping alternatives.

CBT for substance dependence targets five main strategies: identifying triggers for relapse, coping skills training, drug refusal skills training, functional analysis of substance use, and increasing non-use related activities (Kadden et al. 1992). One of the main goals of this therapy is to see drug users 'dis-associate' certain internal and external triggers that are associated with drug use and associated risk behaviours (Kadden 2001).

Studies examining the relationship between CBT treatment and substance use have shown that integrating CBT is associated with better treatment outcomes compared to treatment programmes that do not utilize CBT among participants (Hester and Miller 2003). A more recent systematic review of studies evaluating a wide range of drugs documented statistically significant changes across all substance use related behaviours along with reductions in drug use and continued abstinence from drug use over time among those involved in CBT treatment (Magill and Ray 2009).

The most noticeable changes in behaviour are observed in the first few months of treatment, indicating that CBT treatment can influence large changes among drug users in short periods of time (Magill and Ray 2009). Clinicians generally agree that CBT treatment for drug use should be used in conjunction with other treatments including psychosocial interventions or pharmacological treatment in order to increase a participant's self-efficacy to quit using drugs (Yen et al. 2004).

Contingency management

Contingency management (CM) interventions that aim to treat those using psychoactive and illicit substances are based on

extensive literature and empirical science that looks at drug use and addiction as forms of operant behaviour conditioning, by which behaviour is in some way shaped, or controlled, by its consequences (Higgins and Silverman 1999). The CM approach seeks to use alternative non-drug reinforcers with the aim of decreasing substance use if these reinforcers are prevalent and incompatible with continued drug use and abuse (Carroll et al. 1989; Higgins et al. 1994).

One of the most important aspects of the CM approach is to retain participants in drug treatment programmes (such as detoxification, counselling or opiate substitution treatment), which is associated with greater changes in drug abstinence and associated risk behaviours (Elk et al. 1998). Most models have built upon the premise of retention as one of several incentives (money, vouchers, prizes, etc.), with increasing incentives given to participants the longer they successfully attend drug treatment. When a participant misses an appointment, the incentives are returned to a baseline level (Ledgerwood et al. 2008).

Studies examining the use of CM as a supplementary tool for drug treatment have shown that under treatment, participants significantly reduce drug use, and document increased retention compared to participants who were not offered CM (Rawson et al. 2006). Addiction severity has also been shown to decrease, over time, when CM is incorporated into drug treatment (McLellan et al. 1992). Additionally, the use of CM in methadone maintenance programmes has been associated with longer treatment follow-up periods, higher levels of drug-free urine screens among participants, and better adherence to methadone prescriptions (Griffith et al. 2000).

Short-term contingency management has the potential for dramatic results in short periods of time. However, CM should not be considered a long-term treatment for substance use, as there is evidence of diminishing return as CM is offered over longer periods of time.

Motivational interviewing

Motivational interviewing (MI) is used in clinical settings to motivate change among individuals (Miller and Rollnick 2002), and is used in a wide range of treatment settings for drug users. Treatment for drug users focuses on MI tools including helping clients explore and resolve their ambivalence regarding drug use, and its associated risk behaviours (Miller et al. 2003). Characteristics of MI may include participants expressing commitment, desire, ability, need, readiness, or reasons to change or maintain their drug use habits.

Through a dialogue among drug users and clinicians, MI seeks to extend verbal commitments to change in participants' everyday lives, such that permanent and long-term changes in drug use can be achieved. As motivation for change increases, the focus of MI shifts from commitment toward a development plan for participants. This development plan is put together based on the dialogue collected by clinicians over different MI sessions (Amrhein et al. 2003). Minimizing resistance to change is an important factor in the plan and ensuring participant success (Miller and Rollnick 2002).

Studies evaluating the practice of MI in drug treatment settings have shown that integrating this approach into conventional drug treatment settings is associated with positive changes in drug use and drug use behaviour. A meta-analysis of studies that used MI

for treatment of substance abuse among adolescents found that nearly 70 per cent of included studies documented a positive change when integrating this treatment method (Barnett et al. 2012).

The utilization of MI among participants with substance abuse who are co-infected with HIV has also been evaluated. Participants who were given MI treatment showed significant reduction in their primary illicit drug use after 30 days, and results extended to 60 days after implementation of treatment. Additionally, more significant changes in overall drug use were noted among those who underwent MI along with conventional treatment, compared to those that were not offered supplementary MI sessions (Aharonovich et al. 2012).

Motivational interviewing has become more widely used in many practice settings, and the overall outcome of integrating MI into existing programmes has been positive. By discussing issues related to drug use with participants, along with continued commitments to change, MI has the potential to dramatically reduce drug use when integrated into, or used as a standalone treatment regimen for, drug dependence and other psychological issues.

Residential treatment and detoxification

Detoxification programmes for drug use have been a chosen form of treatment used in a number of countries, and have been used for decades to enable participants to discontinue drug use and associated high-risk behaviour. By placing participants in a programme that does not allow exposure to illicit substances while allowing for treatment of withdrawal symptoms, detoxification programmes have the potential to reduce drug use while also reducing needle use, HIV infection, and seroconversion (Metzger et al. 1993).

Detoxification alone may not be sufficient for participants who are severely dependent on certain substances that cause severe withdrawal symptoms (such as heroin and alcohol) (Mattick and Hall 1996), but is still the chosen first treatment step in the majority of those seeking long-term drug treatment (Kleber and Riordan 1982). In many countries, detoxification now includes the utilization of pharmacological substances to treat withdrawal symptoms, such as methadone or buprenorphine for heroin users, particularly adolescent drug users (Kaminer 1995); this is essential to reducing craving and relapse among participants. However, it is important to continually monitor those in detoxification treatment, especially those who are in outpatient treatment, to ensure continued participation along with abstinence from drug use.

Studies over time have reported positive results when participants are engaged in detoxification, especially when treatment includes medication to treat withdrawal. A systematic review among adolescent substance users reported a higher level of retention along with significant reduction in drug use, after 1 year, when detoxification was initiated in conjunction with pharmacological substance treatment (Minozzi et al. 2009). Even greater reductions in drug use, and greater compliance, were achieved when psychosocial components were integrated into treatment.

However, in detoxification programmes where pharmacological substances are not offered, high rates of relapse and dropout still occur. In Russia, for example, pharmacological treatment is still illegal and as a result high rates of relapse and continued drug use occur among a high percentage of participants who initiate detoxification (Elovich and Drucker 2008). For this reason,

detoxification programmes in most countries now include multidimensional treatment options, to handle not only drug withdrawal and relapse, but also drug cues and triggers related to drug use (Amato et al. 2008).

Early detoxification programmes documented high levels of relapse due to the lack of intervention options for those who need continued treatment. However, as new models for detoxification now include medications, psychosocial components, and other treatment options, higher levels of retention, and significant reductions in drug use, can now be achieved over a long period of time. As a result, social as well as environmental changes can be addressed to reduce the chances of relapse. The earlier someone begins detoxification treatment, the greater chance that permanent change in drug use can be achieved (Kaminer 1995).

Self-help and 12-step programmes for drug use

Self-help, including the 12-step programmes, has been used by many to work through the issues of their drug-taking behaviours through social support and peer discussion. The most common of these programmes for drug users include Narcotics Anonymous (NA) and Cocaine Anonymous (CA) (National Institute on Drug Abuse 2011). All self-help programmes stem from the original 12-step recovery programme of Alcoholics Anonymous set forth in the *Big Book* and the *Twelve Steps and Twelve Traditions* (Alcoholics Anonymous World Services 2002). These programmes help to reduce relapse and drug use through community oriented, 12-step mutual help groups among participants with similar substance abuse problems (Kelly and Myers 2007).

One of the distinctions in self-help programmes is the lack of systematic clinician involvement in treatment. Often, groups are formed among adults, exclusive of formal treatment, although many of the participants in these programmes have come from long-term drug treatment programmes or detoxification centres (Timko et al. 2000). More recently, as adolescent drug use has increased, these programmes have evolved to include adolescent and younger drug users as well.

Twelve-step and self-help programmes offer many positive benefits for drug users. These groups offer unique approaches and ideas for abstinence related behaviours for those that are dealing with drug triggers or cues in their everyday lives. They are also offered at little to no cost, and do not require revealing of personal information to doctors or clinicians. Finally, 12-step and self-help programmes often lead to participants developing a network of fellow ex-users, which can be very helpful as many drug users' previous networks included other drug users, and avoiding these previous networks is an important factor in avoiding relapse (Baer et al. 1993).

Studies among drug users in self-help and 12-step programmes have shown positive results. A recent 3-year study of drug users in self-help programmes showed that over time, many former drug users maintained continuous abstinence from drug use while participating in the programme, and abstinence was greater the more sessions that were attended (Laudet 2007). A study among adolescents in inpatient treatment followed by participation in self-help programmes found that abstinence was greater the more sessions that were attended (Kelly et al. 2004).

Self-help programmes have evolved over time from the original programmes focused on alcohol to encompass many different drugs of abuse. Along with complementary treatment including

detoxification and pharmacological therapy, self-help programmes have the potential to bring together users while keeping them in networks of other users who are also trying to stop using drugs. By attending these meetings and avoiding cues and triggers that may lead to drug use and associated risk behaviours, longer periods of treatment success can be achieved.

Harm reduction and human rights

Harm reduction

The emergence of HIV/AIDS among injecting drug users has been a profound challenge to public health systems. In some areas, there was a rapid response, and potential HIV epidemics among IDUs were averted. In other areas, HIV epidemics occurred before effective public health responses, but the responses eventually brought the epidemics under control, and in still other areas, HIV epidemics are occurring among PWID without any effective public health response. The HIV/AIDS crisis has furthered the development of a policy framework that provides a new perspective on the use of psychoactive drugs (both licit and illicit). This perspective has generally come to be known as 'harm reduction' (Buning 1991; Berridge 1999).

One of the most well-known harm reduction programmes, needle and syringe exchange programmes (NSP), has been in operation for many years in high-income locations and has begun to emerge in low- and middle-income countries in recent years. A systematic review of structural level NSP (structural NSP distribute at least ten needles/syringes per PWID per year) in low- and middle-income countries completed in 2013 documented noticeable reductions in both HIV and HCV infections among PWID in conjunction with the implementation and scale up of NSP. More noticeable changes were especially noticeable when more needles were made available per PWID in a particular location (Des Jarlais et al. 2013).

It may be best to present harm reduction in the words of its practitioners (Harm Reduction Coalition (n.d.): 'Harm reduction is a set of practical strategies that reduce negative consequences of drug use, incorporating a spectrum of strategies from safer use, to managed use, to abstinence. Harm reduction strategies meet drug users "where they're at," addressing conditions of use along with the use itself'.

Because harm reduction demands that interventions and policies designed to serve drug users reflect specific individual and community needs, there is no universal definition of or formula for implementing harm reduction. However, the Harm Reduction Coalition considers the following principles central to harm reduction practice (Harm Reduction Coalition 2007):

Accepts, for better and for worse, that licit and illicit drug use is part of our world and chooses to work to minimize its harmful effects rather than simply ignore or condemn them.

Understands drug use as a complex, multi-faceted phenomenon that encompasses a continuum of behaviors from severe abuse to total abstinence, and acknowledges that some ways of using drugs are clearly safer than others.

Establishes quality of individual and community life and well-being—not necessarily cessation of all drug use—as the criteria for successful interventions and policies.

Calls for the non-judgmental, non-coercive provision of services and resources to people who use drugs and the communities in which they live in order to assist them in reducing attendant harm.

Ensures that drug users and those with a history of drug use routinely have a real voice in the creation of programs and policies designed to serve them.

Affirms drugs users themselves as the primary agents of reducing the harms of their drug use, and seeks to empower users to share information and support each other in strategies which meet their actual conditions of use.

Recognizes that the realities of poverty, class, racism, social isolation, past trauma, sex-based discrimination and other social inequalities affect both peoples' vulnerability to and capacity for effectively dealing with drug-related harm.

Does not attempt to minimize or ignore the real and tragic harm and danger associated with licit and illicit drug use.

The two basic components of harm reduction are utilizing evidence-based interventions to reduce the adverse individual and societal consequences of drug use and respecting the civil rights of drug users (Des Jarlais 1995; Gilmore 1996; Elliott 2004; Wolfe and Malinowska-Sempruch 2004). An important insight of harm reduction is that many of the adverse consequence of drug use can be addressed among persons who continue to use drugs. This is critical because while there are effective treatments to reduce drug use among persons with SUDs, our ability to achieve permanent abstinence among persons who use drugs is quite limited and likely to remain so for the indefinite future.

Harm reduction has a moral component in addition to its evidence-based component. Health should be considered a fundamental human right of persons who use drugs (Wood et al. 2010). Given the structure of the human nervous system, it is very unlikely that we will ever have a world without problems associated with drug use. Denying the human rights of drug users, however, will only make the problems worse.

Alcohol

Robin Room

Alcohol and its effects

Alcoholic beverages have been consumed in most, if not all, human societies since the beginning of recorded history. Beverages containing ethanol (C_2H_5OH) can be fermented from a large number of organic materials that comprise carbohydrates, and in one part of the world or another, these products are prepared from fruits, berries, various grains, plants, honey, or milk. Under most circumstances, such fermented beverages can contain up to 14 per cent ethanol. The most widely commercialized fermented beverages are beer prepared from barley or other grains (usually 3–7 per cent ethanol), apple and other fruit ciders (usually 3–7 per cent ethanol), and grape wine (usually 8–14 per cent ethanol). Other fermented beverages are also common in particular cultures, often from home production or in commercial form: for example, sorghum or millet beers in Eastern and Southern Africa, palm wine toddy in West Africa and the Indian subcontinent, pulque (prepared from the maguey cactus) in Mexico, and rice wine (sake) in Eastern Asia.

Distilled beverages, in which ethanol is concentrated by evaporation and condensation from a fermented liquid, came to Europe from Arabia in the Middle Ages. In Europe, at first, their use was primarily medicinal, but by the 1600s, popular use as a social beverage spread rapidly. Distilled beverages can be made up of almost-pure ethanol, but those sold for drinking usually contain between 25 per cent and 50 per cent ethanol. Distilled alcohol is also added to wine, producing ‘fortified wines’ with about 20 per cent ethanol. Because distilled beverages and fortified wines do not readily spoil, they could be shipped over long distances, even before refrigeration and airtight packaging became available, and played a particularly important part in commerce and exploitation in the age of the European empires. Different cultures consume varying strengths of alcoholic beverages, often with water or a ‘mixer’ being added to distilled beverages and, in some cultures, also to wine and other fermented beverages.

Use-values of alcohol

Ethanol has many uses in human life. These include non-beverage uses as a fuel and as a solvent. Important beverage-related use-values include use as a medicine, as a religious sacrament, as a foodstuff, and as a thirst-quencher (Mäkelä 1983). But, alcoholic beverages have received special attention as a public health hazard because of their psychoactive properties. These properties carry with them another set of use-values: in terms of psychopharmacology, ethanol is a depressant, and alcoholic beverages have long been used to affect mood and feelings. With enough consumption,

alcohol becomes an anodyne and, indeed, an anaesthetic; distilled spirits were used as an anaesthetic in surgical practice before the mid-nineteenth century. Many drinkers seek and appreciate the levels of intoxication which lie between mild mood alteration at one end of the spectrum and being comatose at the other.

The decisions to drink and how much to drink are, however, often not made by the individual in isolation. Drinking is usually a social act, and the pace and level of drinking are frequently subject to collective influence, with drinking together being seen as an expression of solidarity and community. Although drunkenness may be sought to relieve misery or loneliness, it is more commonly associated with sociable celebration.

Adverse effects

Alcohol consumption can have a variety of adverse effects, some of which are acute effects associated with the particular drinking event. Drinking progressively impairs physical coordination, cognition, and attention, resulting in an increased risk of accidents and injury. Above a threshold level, drinking can also affect intention and judgement, so intoxication potentially plays a causal role in violent behaviour and crime (Graham et al. 1998). This relation appears to be culturally mediated, because there is a substantial variation between cultures in the association of intoxication with violence and crime (Room 2001). A sufficient amount of alcohol may result in a potentially fatal overdose, by interrupting various autonomic bodily functions.

Other adverse effects of alcohol consumption are chronic effects related to a repeated pattern of drinking. Alcohol consumption can adversely affect nearly every organ of the body, although some effects are not common. Chronic conditions in which alcohol is implicated as an important cause include liver cirrhosis; cancers of the upper digestive tract, liver, and breast; cardiomyopathy; and gastritis and pancreatitis (Rehm et al. 2010). Through a variety of mechanisms, alcohol is also implicated in the incidence and course of infectious diseases (Parry et al. 2009).

Repeated heavy drinking can also adversely affect mental health; specific neurological disorders are associated with sustained heavy drinking. More common concomitants include depression and affective disorders. Alcoholism—the experience of loss of control over drinking, along with other psychological and physical sequelae—has also been considered a mental disorder in modern times. In current nosologies, alcoholism has been replaced by the terms *alcohol use disorder* (in *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM5) terminology) and the *alcohol dependence syndrome* (in the *International Classification of Diseases*, 10th edition (ICD-10)).

The impairment of coordination and judgement produced by drinking potentially affects bystanders and the drinkers' acquaintances, friends, and family, as well as themselves: the effects can be through impairment of coordination or judgement during the drinking event, resulting in injury or distress, or through impairment of performance in family, friendship, work, and other social roles as a result of recurring drinking episodes (Laslett et al. 2011). The actual and potential adverse effects on others have historically been the primary justification for alcohol controls and other societal responses to problematic drinking (Room 1996); the effects on the adult drinker's own health have been of much less importance in determining public policy on alcohol.

Positive effects

For the drinker, and sometimes for those around, alcohol consumption can have positive effects. We have already mentioned the different use-values of alcohol—which mean that drinkers are usually willing to pay more than just the cost of production and distribution of the beverage. Apart from its valued effects on mental state, alcohol use has some positive outcomes on health. By far the most important of these, in terms of public health, is its potential for preventing cardiovascular disease (CVD). A fairly consistent finding in studies in several societies is that drinking at moderate levels protects against CVD (Klatsky 1999), although controversy about the existence and extent of this effect remains (e.g. Fillmore et al. 2006). The findings on the upper limit of drinking for such protection vary. Taken together, it appears that most of the protective effect can be gained with as little as one drink of an alcoholic beverage every second day (Maclure 1993). About half of this effect seems to come from inhibiting the build-up of plaque in arteries, whereas the other half seems to result from a relatively immediate effect of diminishing the likelihood of blood clots. To the extent this is true, irregular or occasional drinking is likely to have less protective effect.

Although it has been argued that this protection comes primarily from red wine constituents (particularly resveratrol) rather than from the ethanol, the balance of evidence favours an ethanol effect (Klatsky 1999). However, relatively little is known about how this effect interacts with or overlaps other risk and protective factors for chronic heart disease (CHD), such as regular exercise, diet, or taking aspirin (acetylsalicylic acid) or other pharmaceuticals (Criqui et al. 1998). The protective effect of alcohol appears to be higher for cigarette smokers than for non-smokers (Kozlowski et al. 1994).

Drinking is also often bad for the heart (Chadwick and Goode 1998; Poikolainen 1999). Studies have found that a pattern of intermittent heavy drinking, such as getting drunk every weekend, is associated with an elevated rate of coronary death (Kauhanen et al. 1997; Bagnardi et al. 2008), probably through mechanisms such as heart arrhythmias (Kupari and Koskinen 1998; McKee and Britton 1998). Data from countries in the former Soviet Union, where a pattern of intermittent intoxication is common, support the strong adverse effect of binge drinking on heart disease mortality (Rehm and Room 2009; Zaridze et al. 2011). During a period of deliberate restriction of alcohol supplies, the estimated per capita consumption in Russia, including the illicit alcohol market, fell from 14.2 L in 1984 to 10.7 L in 1987 (Shkolnikov and Nemtsov 1997)—a fall of 25 per cent. The death rate from ischaemic heart disease among males fell by 10 per cent

in the same period (Leon et al. 1997). This rate rose again when the restrictions lapsed, although this time, unlike between 1985 and 1988, other risk factors also changed.

Research on cumulative effects of alcohol

Effects on the drinker's health

In most studies, the relationship between amount of drinking and overall mortality is a J-shaped curve, with abstainers, and often, very light drinkers showing a higher mortality than those drinking a little more. This may be because, in these findings, a substantial part of the study population were older adults, and thus were at risk of mortality from CVD. Studies limited to younger cohorts typically found a monotonic relationship between amount of drinking and mortality (Andréasson et al. 1991; Rehm and Sempos 1995). Such an association might also be expected in any population, such as in some developing countries, that has a low rate of CVD.

The pattern of drinking is also a potentially important factor in mortality due to alcohol. Although this has long been obvious in casualty deaths, there is growing recognition of its significance in other causes of death, as implied by the earlier-mentioned Russian data. However, until recently, there have been only few measurements of this pattern in studies on alcohol and overall mortality. Variations among cultures in drinking habits may partly explain why the J-curve relation of volume of drinking to mortality shows different low-points in different cultures.

The risks and potential benefits associated with a given level of drinking, thus, vary with the age and sex of the drinker, and possibly with other sociocultural characteristics, as well as with the pattern and circumstances related to drinking. This variation has posed a considerable challenge because of political demand in a number of countries for advice on 'low-risk drinking' or 'safe drinking' guidelines. Whereas earlier guidelines were inclined to be stated only in terms of the volume of drinking, in line with the measurement methods of medical epidemiology literature, more recent guidelines have also emphasized limits on the amount consumed on a given occasion or day (Stockwell and Room 2012).

Current literature on the cumulative effects of drinking on health relies substantially on summations of prospective epidemiological literature, following the tradition set up by English et al. (1995). Using meta-analysis on studies of the relationship between volume of drinking and specific causes of death in which alcohol was either a risk or protective factor, the studies following this tradition derive attributable fractions for different levels of the volume of drinking and apply these fractions to segments of the population at each level in order to arrive at estimates on total lives and life-years lost and gained, subtracting the projected protective effects of alcohol from the negative burden. In addition to life-years lost, the study's most comprehensive indicator, disability-adjusted life years (DALYs), includes a projection of the burden of disability attributable to alcohol.

According to estimates for 2010, 3.9 per cent of the total burden of disease globally (as measured in DALYs) is attributable to alcohol (Lim et al. 2012). This compares with 6.3 per cent for tobacco and 1.0 per cent for illegal drugs. As earlier estimates showed (Ezzati et al. 2002), the alcohol share of the burden is highest in high-income societies, including Eastern Europe and Northern Asia, as well as in Latin America. The relative position of alcohol

among risk factors is actually highest in middle-income countries, where it ranks first; although the alcohol share of all DALYs is lower in other developing regions, this fraction is calculated on the basis of a higher total burden of disease and disability in these countries.

Effects at the population level

So far, we have dealt with estimates of alcohol's effects at the individual level. The methodological difficulties in the studies underlying these estimates extend beyond those we have already discussed (Edwards et al. 1994). The estimates rely primarily on prospective epidemiological studies in which alcohol consumption is measured at one point in time; such a measurement is, at best, a poor surrogate for either of the main aspects of alcohol consumption as a risk factor—chronic effects of cumulated alcohol consumption or acute effects of intoxication at a specific event. In these studies, the effects of possible confounders are dealt with by statistically controlling for them in the analysis. But this can be problematic if drinking and the potential confounder are causally intertwined, as is true in the case of hypertension or tobacco smoking. Consider, for instance, a person who only smokes when under the influence of alcohol; controlling for that person's smoking behaviour potentially obscures some of the alcohol effect.

From a public health perspective, it is the effects at the population level, rather than the individual level, that are the main concern. If drinking was entirely a matter of individual choice and behaviour, and if the effects of drinking happened only to the drinker, then effects at the population level would be a simple aggregation of the effects at the individual level. But neither of these conditions is applicable. Drinking is by and large a social activity, and the drinking behaviour of a person is likely to influence and be influenced by those around that person. In a given population, the amounts drunk by infrequent or light drinkers and by heavy drinkers tend to move up and down in concert. Thus, if there is some health gain when those at the lower end of the spectrum increase their consumption, there will also be health losses from an increase in consumption for those at the top end of the spectrum. In view of this, it has been argued that the level of per-drinker consumption where the balance of health benefits and losses is optimized in a population is likely to be considerably lower than the optimum level of consumption for the individual drinker (Skog 1996). For instance, Skog (1996) argued that the optimum level of alcohol consumption with respect to mortality was likely to be lower than the present-day per-capita consumption of any nation in Western Europe. His argument is supported by findings of a generally positive relationship of the level of alcohol consumption with total mortality in time-series analysis of differenced data in a number of high-income countries (Norström and Ramstedt 2005).

By their design, the prospective studies typically used for investigations of alcohol's effects on mortality or morbidity do not measure the effects of drinking on others. Other types of individual-level studies, such as studies of the effects of drinking-driving (Perrine et al. 1989) or studies of homicide and other crimes (Wolfgang 1958), document the importance of such effects in terms of death or injury. But the strongest evidence of the magnitude of these effects comes from aggregate-level studies of the covariation of changes over time in a given society or place. Differenced time-series analyses in European societies

have suggested that a 1 L change in per capita alcohol consumption produces about a 1 per cent change in the overall mortality rate (Her and Rehm 1998; Norström 1996). Here again, however, drinking patterns and social circumstances are likely to make a difference. For instance, the drop in Russian total mortality during the alcohol restrictions of 1985–1988 implies a decline of about 2.7 per cent in age-standardized mortality for each 1 L drop in per capita consumption (calculated from Shkolnikov and Nemtsov (1997) and Leon et al. (1997)). Even specifically for heart disease, any protective effects from changes in low-level drinking seem to be outbalanced in the population as a whole by negative effects from changes at high-consumption levels, levels of consumption typical in high-income societies. Thus, time-series analyses of differenced data on alcohol consumption and on CHD mortality in 14 European countries found no evidence of net protective effects and some evidence of net adverse effect (Hemström 2001; Ramstedt 2006).

Alcohol as an issue in public health

Shifting societal responses to problematic drinking

Efforts to control problematic drinking date back to the beginning of recorded history. These efforts have been many-sided, including informal responses in the family and community, as well as governmental controls. Religious teachings and movements have often been directed against drinking or intoxication: Moslems are forbidden by their faith to drink at all, and drinking is also discouraged or forbidden in at least some branches of all the major world religions.

In the last few centuries, European and Europe-derived societies have been hosts to conflicting trends in terms of alcohol issues. The production of alcoholic beverages became an important part of European economies and of imperial domination and trade in the age of European colonization. Alcohol production and exports took on political importance not only in the wine cultures of Southern Europe, but also in such countries as the Netherlands and Britain. In America, in the late-eighteenth century, distilled spirits was the only profitable way to get grain to market (Rorabaugh 1979). In recent decades, alcohol beverage industries have become increasingly internationalized and concentrated (Jernigan 2010), and multinational companies, mostly based in Europe or North America, have pressed with considerable success to open up global markets for alcohol.

Starting in the early 1800s, there were substantial waves of popular, and eventually, governmental response to the problems that were resulting from the very heavy consumption of alcoholic beverages in English-speaking and Northern European societies (Blocker 1989; Levine 1991). As a culmination of decades of popular temperance movements, in the early twentieth century, alcohol prohibition was adopted in 13 countries (Schrad 2010) and imposed on indigenous people in colonial territories, and stringent controls were placed on the availability of alcohol in some other countries. Although alcohol's impact on public order and morals and on family life were more central to the temperance movement thinking than the public health issues, mainstream thought in medicine and public health acknowledged the substantial adverse impacts of alcohol on health (Emerson 1932), and prohibition or an alternative, stringent controls on the availability of alcohol (Catlin 1931), were often identified with the public health interest.

In the United States, and some other societies which had prohibited or greatly restricted alcohol availability, there was a strong reaction against it by the early 1930s, with middle-class youth in the lead (Room 1984a, 1984b). In this cultural-political context, as the new generation moved into professional and research positions, adverse effects of alcohol were downplayed or denied (Herd 1992; Katcher 1993), and alcohol issues almost disappeared from public health textbooks and discourse. Any problems with drinking were seen as attributable to a relatively small cadre of alcoholics, unable to control their drinking because of a mysterious predisposing factor. As late as 1968, the main emphasis of the American Public Health Association was on building treatment capacity for alcoholism (Cross 1968).

The 'new public health' approach

The last three decades of the twentieth century saw the rise of what has been termed in the alcohol literature the 'new public health' approach (Beauchamp 1976; Tigerstedt 1999) to alcohol issues. This approach brought together several strands of research and philosophy. In contrast to a concept in terms of 'alcoholism', the approach was premised on a disaggregated approach: there was a diversity of alcohol-related problems, fairly widely distributed among the drinking population (Knupfer 1967; World Health Organization (WHO), Expert Committee on Problems Related to Alcohol Consumption 1980). It was noted that for many problems, the heaviest drinkers accounted for only a minority, because there were so many more drinking at somewhat lower levels (Moore and Gerstein 1981); picking up Rose's (1981) phrase, Kreitman (1986) termed this the 'preventive paradox'. Attention was, therefore, paid not only to the heaviest drinkers, but also to the whole range of drinking levels, and indeed, to the distribution of consumption in the population (Ledermann 1956; De Lint and Schmidt 1968). What happens with moderate drinkers, it was argued, influences the social climate for heavy drinking, because drinking is largely a social activity, marked by mutual influences and norms of reciprocity (Bruun et al. 1975a; Skog 1985). In a given population, it was found that rates of alcohol-related problems tend to rise and fall with changes in the level of consumption (Seeley 1960). Controls on the availability of alcohol, including taxes, affect the level of consumption, and thus, also the rates of alcohol-related problems (Seeley 1960; Terris 1967; Popham et al. 1976). The level of alcohol consumption in a population, and controls on alcohol availability, is thus seen as a public health concern, and part of a society's overall 'alcohol policy' (Bruun et al. 1975a).

In enumerating the elements of the new public health approach, we have given references for early statements of each element. It will be seen that the strands of this approach were woven together gradually over a period of some years. A 1975 report by an international group of researchers (Bruun et al. 1975a) became a pivotal document for the approach. A few years later, the approach was given an authoritative endorsement in the United States by a committee of the National Academy of Sciences (Moore and Gerstein 1981). The most recent restatement of the approach by an international group of scholars appeared in 2010 (Babor et al. 2010), with a somewhat parallel analysis oriented to the developing world (Room et al. 2002).

The approach has had considerable influence on WHO programmes in the field of alcohol (Room 2005; WHO 2007). For instance, action on the availability and marketing of alcohol and

on pricing policies are key elements of WHO's Global Strategy to Reduce the Harmful Effects of Alcohol, adopted in 2010 (WHO 2010). At national levels, there has been a considerable variation in its influence on policy. In Sweden, where it is known as the Total Consumption Model, it attained dominance as the basis for official policy (Sutton 1998). However, policies based on this approach have been eroded as a consequence of Sweden's accession to the European Union (Holder et al. 1998). The approach also has had considerable backing in other Nordic countries.

In English-speaking countries, it has encountered substantial resistance in the cultural-political realm. Those allied with the alcoholic beverage industry have strongly attacked the approach, both in analyses and polemics (e.g. Mott 1991; Grant and Litvak 1998) and through direct political action to remove official proponents (Room 1984c). An approach that contemplates government regulation and influencing of private consumer choices is also unwelcome to those committed to consumer sovereignty and the primacy of individual choice (e.g. Peele 1987). Often, proponents of approaches seeking to 'domesticate' drinking—to reduce problems from drinking by integrating it into everyday life—have portrayed the new public health approach as antithetical to this (Olsson 1990), although some researchers have noted that there is no necessary antithesis (Whitehead 1979).

In terms of its influence on policy, the approach has undoubtedly had some effect in strengthening the defence of existing control structures and regulations. But efforts to get the approach adopted as the practical base for policy have met with resistance and failure in a number of countries (Hawks 1993; Room 2004). One response to this resistance has been some calls for an alternative approach (Stockwell et al. 1997), arguing that policy measures directed at heavy and problematic drinkers are more politically acceptable than measures directed at all drinkers.

The policy approach offered as an alternative is a focus on harm reduction, primarily by reducing instances of intoxication or insulating the drinkers from harm (Plant et al. 1997; Stimson et al. 2007). However, there is in fact usually no conflict between approaches aimed at total consumption and approaches aiming to reduce harm from heavy drinking. As Stockwell et al. (1997) noted, 'aggregate consumption levels are in fact likely to fall if effective [harm reduction] strategies are introduced' (p. 6). Conversely, many measures that affect the whole drinking population—taxation being a good example—are especially hard on heavier drinkers. Nor are targeted harm reduction measures necessarily more politically acceptable than measures that affect all drinkers. Old systems of rationing and individual buyer surveillance (Järvinen 1991), which were directed specifically at restraining heavy drinking, are now politically unacceptable in any high-income society, although rationing, at least, was highly effective as a targeted prevention measure (Norström 1987). Thus the first act of a new government elected in Australia's Northern Territory was to dismantle a new system requiring electronic identification to purchase alcohol, which had put into effect a ban on alcohol purchases by specific problematic drinkers (Room 2013).

Beyond its specific features, the controversy over the new public health approach replicates familiar patterns of controversy over public health approaches in general, particularly when those approaches impinge on familiar and valued patterns of behaviour, with substantial economic interests at stake. At the level of the knowledge base, the approach has had considerable success: The

empirical evidence underlying the approach has considerably strengthened since the approach was first put forward. At a political level, however, the approach has had only limited success, and primarily in areas peripheral to its main focus—that is, in drinking-driving and minimum-age limits for drinkers.

Strategies of prevention and control and their effectiveness

Simplifying them, there are seven main strategies to minimize alcohol problems. One strategy is to educate or persuade people not to use alcohol or about ways to use it so as to limit harm. A second strategy, a kind of negative persuasion, is to deter drinking-related behaviour with the threat of penalties. A third strategy, in the positive direction, is to provide alternatives to drinking or to drink-related activities. A fourth strategy is in one way or another to insulate the user from harm. A fifth strategy is to regulate availability of alcohol or the conditions of its use; prohibition of supply may be regarded as a special case of such regulation. A sixth strategy is to work with social or religious movements oriented to reducing alcohol problems. And, a seventh strategy is to treat or otherwise help people who have trouble with their drinking habits. We will consider, in turn, these strategies and the evidence on their effectiveness.

Education and persuasion

In principle, education can be offered to any segment of the population in a variety of venues, but it is usually education of youth in schools that first comes to mind in the prevention of alcohol problems. Community-based prevention programmes, which are often also directed at adults, also may include an educational component.

Education offers new information or ways of thinking and leaves it to the listener to draw conclusions concerning beliefs and behaviour. However, most alcohol education programmes go beyond this. A common theme in North American evaluative literature on alcohol education is that ‘knowledge-only’ approaches do not result in changes in behaviour (Botvin 1995). School-based alcohol education has, thus, usually had a persuasional element, aiming to influence students in a particular direction.

Persuasion is directly concerned with changing beliefs or behaviours, and may or may not also offer information. Mass media campaigns aimed at persuasion have been a very common component of prevention programmes for alcohol-related problems, but this can also be pursued through other media and modalities.

In most societies, public health-oriented persuasion about alcohol must compete with a variety of other persuasive messages, including those intended to sell alcoholic beverages. The evidence that alcohol advertising influences teenagers and young adults towards increased drinking and problematic drinking is becoming stronger (Casswell et al. 2002). Even where alcohol advertising is not allowed in the mass media, these messages are often conveyed to consumers and potential consumers in a variety of other ways.

Evidence on effectiveness

The literature on effectiveness of educational approaches is dominated by studies on school-based education from the United States. This means that alcohol education has usually been in the

context of drug and tobacco education and that the emphasis has been on abstinence (Beck 1998) or at least on delaying the start of drinking, in cultural circumstances where the median age of actually starting to drink is about 13 years although the minimum legal drinking age is 21 years. In general, despite the best efforts of a generation of researchers, this literature has had difficulty showing substantial and lasting effects (Foxcroft et al. 2003; Gorman et al. 2007). There is a good argument from general principles for alcohol education in the context of consumer and health, but there is little evidence from the formal evaluation literature at this point of its effectiveness beyond the short term (Babor et al. 2010).

Persuasive media campaigns have also been a favourite modality in many places in recent decades. In general, evaluations of such campaigns have been able to demonstrate impacts on knowledge and awareness about substance use problems, but show little success in affecting attitudes and behaviours (Babor et al. 2010). As with school education approaches, there are hints in literature that more success may come from influencing the community around the drinker—in terms of attitudes of significant others or popular support for alcohol policy measures—than from directly persuading the drinker himself or herself. Thus, media messages can be effective as agenda-setting mechanisms in the community, increasing or sustaining public support for other preventive strategies (Casswell et al. 1989).

Deterrence

In its broadest sense, deterrence means simply the threat of negative sanctions or disincentives for behaviour—a form of negative persuasion. Criminal laws deter in two ways: by general deterrence, which is the effect of the law in preventing a prohibited behaviour in the population as a whole; and specific deterrence, which is the effect of the law in discouraging those who have been caught from doing it again (Ross 1982). A law will have a greater preventive effect and be cheaper to administer to the extent it has a strong general deterrence effect.

Prohibitions on driving after drinking more than a specified amount are now in effect in most nations (WHO 2004). In many societies, there have also been laws against drinking in public places, against public drunkenness (being in a public place while intoxicated) and against obnoxious behaviour while intoxicated. Other common prohibitions are concerned with producing or selling alcoholic beverages outside state-regulated channels and with aspects of drinking under a specified minimum age.

Evidence on effectiveness

Drinking-driving legislation, such as ‘per se’ laws outlawing driving while at or above a defined blood-alcohol level, has been shown to be effective in changing behaviour and reducing rates of alcohol-related problems (Ross 1982; Hingson 1996; Babor et al. 2010). The effect is through both general and specific deterrence. The quickness and certainty of punishment as well as its severity are important in the deterrent value (too much severity tends to undercut the quickness and certainty). Drinking-driving is an ideal area for applying general deterrence, as the gains from breaking the law are limited and automobile drivers typically have something to lose by being caught.

Many English-speaking and Scandinavian countries have had a tradition of criminalizing drinking in public places or public drunkenness as such. The trend in the 1970s and following was

to decriminalize public drunkenness, although in many places it remains illegal. In the 1990s and following, there has been some trend to criminalize drinking in specific public places (Pennay and Room 2012). Criminalization of such behaviours has some effect in moving behaviour around, but is not very effective in changing the behaviour of marginalized heavy drinkers who have little to lose.

Providing and encouraging alternative activities

Another strategy, in principle involving positive incentives, is to provide and seek to encourage activities that are an alternative to drinking or to activities closely associated with drinking. This includes initiatives such as making soft drinks available as an alternative to alcoholic beverages, providing locations for sociability as an alternative to taverns, and providing and encouraging recreational activities as an alternative to leisure activities involving drinking. Job creation and skill development programmes are other examples.

Evidence on effectiveness

'Boredom' and 'because there's nothing else to do' are certainly among the reasons given by some for drinking. And, there are often good reasons of general social policy for providing and encouraging alternative activities. But as has been noted, the problem with alternatives to drinking is that drinking combines so well with many of them. Soft drinks are indeed an alternative to alcoholic beverages for quenching thirst, but they may also serve as a mixer in an alcoholic drink. Involvement in sports may go along with drinking as well as replace it. The few evaluation studies of providing alternative activities, again from a restricted number of societies, have generally not shown lasting effects on drinking behaviour (Moskowitz et al. 1983; Norman et al. 1997), although they undoubtedly often serve a general social purpose in broadening opportunities for the disadvantaged (Carmona and Stewart 1996).

Insulating use from harm

A major social strategy for reducing alcohol-related problems in many societies has been measures to separate the drinker, and particularly heavy drinkers, from potential harm. This separation can be physical (in terms of distance or walls), it can be temporal, or it can be cultural (e.g. defining the drinking occasion as 'time out' from normal responsibilities). These 'harm-reduction' strategies, as they are called in the context of illicit drugs, are often built into cultural arrangements around drinking, but can also be the object of purposive programmes and policies (Moore and Gerstein 1981), such as promotion of 'designated drivers', where one person in a social group is chosen to abstain and drive in the particular social situation (DeJong and Hingson 1998).

A variety of modifications to the driving environment positively affect casualties associated with drinking and driving, along with other casualties. These include mandatory use of seat belts, airbags, and improvements in the safety of vehicles and roads. Many other practical measures to separate intoxication episodes from casualties and other adverse consequences have been put into practice, although usually without formal evaluation.

Evidence on effectiveness

Drinking-driving countermeasures are a prime example of an approach in terms of insulating drinking behaviour from harm, as they seek to reduce alcohol-related traffic casualties without necessarily stopping or reducing alcohol use (Evans 1991). There is substantial evidence on the success of a range of such countermeasures, including environmental change approaches as well as deterrence (DeJong and Hingson 1998; Babor et al. 2010). Some environmental measures that reduce traffic casualties in general—such as requiring the wearing of seat belts in cars or providing sidewalks separated from the road—may prevent casualties associated with intoxication even more than other casualties.

Regulating the availability and conditions of use

In terms of the substantial harm to health and public order they can cause, alcoholic beverages are not ordinary commodities. Governments have, thus, often actively intervened in the markets for such beverages, far beyond usual levels of state intervention in markets for commodities.

Total prohibition can be viewed as an extreme form of regulation of the market. In this circumstance, where no one is licensed to sell alcohol, the state has no formal control over the conditions of the sales that occur nevertheless, and there are no legal sales interests, controlled through licensing, to cooperate with the state in market regulation.

With a general prohibition, typically, the consumption of alcohol does fall in the population, and there are also declines in the rates of the direct consequences of drinking such as cirrhosis or alcohol-related mental disorders (Moore and Gerstein 1981; Teasley 1992). But prohibition also brings with it characteristic negative consequences, including the emergence and growth of an illicit market and the crime associated with this. Partly for this reason, alcohol prohibition at a national level is now a live option only in Islamic societies, where the law reflects religious belief, which helps to sustain compliance. Local-area alcohol prohibitions are more widespread.

The features of alcohol control regimes that regulate the legal market in alcohol vary greatly. Special taxes on alcohol are very common, imposed often as much for revenue as for public health considerations. Most societies have minimum-age limits forbidding sales to underage customers and many have regulations forbidding sales to the already intoxicated. Often, the regulations include limiting the number of sales outlets, restricting hours and days of sale, and limiting sales to special stores or drinking places. Rationing of alcohol purchases—limiting the amount individuals can buy in a given time period—has also been used as a means of regulating availability. Regulations restricting or forbidding advertising of alcoholic beverages attempt to limit or channel efforts by private interests to increase demand for particular alcoholic beverages. Such regulations potentially complement education and persuasion efforts. State monopolization on sales of some or all alcoholic beverages at the retail and/or wholesale level has also been commonly used as a mechanism to minimize alcohol-related harm (Room 1993).

Effectiveness of specific types of regulation on availability

The decades since the 1970s have seen the development of a burgeoning literature on the effects of alcohol control measures.

Reference guides for communities, summarizing the research evidence and attuned to particular national or regional conditions, are becoming available (e.g. Neves et al. 1998; Grover 1999). Specific types of regulation of the alcohol market, and the evidence on their effectiveness, are discussed as follows:

Minimum-age limits

A minimum-age limit is a partial prohibition, applied to one segment of the population. There is a strong evaluation literature showing the effectiveness of establishing and enforcing minimum-age limits in reducing alcohol-related problems (Babor et al. 2010). However, this literature is mostly based on North America, focusing mostly on youthful driving casualties and evaluating reduction from and increases to age 21 years as the limit, a minimum-age limit higher than in most societies. There is limited evidence on the applicability of the literature's findings in other societies and where youth cultures may be less automobile-focused (but see Møller 2002; Kypri et al. 2006).

Taxes and other price increases

Generally, consumers show some response on the price of alcoholic beverages, as on all other commodities. If the price goes up, the drinker will drink less; data from high-income societies suggests this is at least as true of the heavy drinker as of the occasional drinker (Babor et al. 2010). Studies have found that alcohol tax increases reduce the rates of traffic casualties, of cirrhosis mortality, and of incidents of violence (Cook 2007).

Limiting sales outlets and hours and conditions of sale

A substantial body of literature shows that levels and patterns of alcohol consumption, and rates of alcohol-related casualties and other problems, are influenced by such sales restrictions, which typically make the purchase of alcoholic beverages slightly inconvenient or influence the setting of and after drinking (Babor et al. 2010; Livingston 2013). Enforced rules influencing 'house policies' in drinking places on not serving intoxicated customers, for example, have also been shown to have some effect (Saltz 1997).

Monopolizing production or sale

Studies of the effects of privatizing retail alcohol monopolies have often shown some increase in levels of alcohol consumption and problems, in part because the number of outlets and hours of sale typically increase with privatization (Her et al. 1999) and partly also because the new private interests typically exert political influence for further increases in availability. From a public health perspective, it is the retail level that is important, although monopolization of the production or wholesale level may facilitate revenue collection and effective control of the market.

Rationing sales

Rationing the amount of alcohol sold to an individual potentially directly impacts on heavy drinkers and has been shown to reduce levels both of intoxication-related problems such as violence and of drinking-history-related problems such as cirrhosis mortality (Schechter 1986; Norström 1987). But, although a form of rationing—the medical prescription system—is well accepted in most societies for psychoactive medications, it has proved politically unacceptable nowadays for alcoholic beverages in high-income societies.

Advertising and promotion restrictions

Many societies have regulations on advertising and other promotion of sales of alcoholic beverages (WHO 2004). Although it is well accepted that advertising can strongly affect consumer choices on products in the market, it has proved difficult to measure the effects of advertising on demand for alcoholic beverages as a whole, partly because the effects are likely to be cumulative and long-term, making them difficult to measure. However, the evidence on the effects of advertising and promotion on overall demand has become somewhat stronger in recent literature (Casswell 1995; Casswell and Zhang 1998; Babor et al. 2010).

Social and religious movements and community action

Substantial reductions in alcohol-related problems have often been the result of spontaneous social and religious movements, which put a major emphasis on quitting intoxication or drinking. In recent decades, efforts have also been made to form partnerships between state organizations and non-governmental groups to work on alcohol problems, often at the level of the local community. There has been an active tradition of community action projects on alcohol problems, often using a range of prevention strategies (Giesbrecht et al. 1990; Greenfield and Zimmerman 1993; Holmila 1997; Holder 1998). School-based prevention efforts have also moved increasingly to try to involve the community, in line with general perceptions that such multifaceted strategies will be more effective (Paglia and Room 1999).

Although some of the biggest historical reductions in alcohol problem rates have resulted from spontaneous and autonomous social or religious movements, support or collaboration from a government can easily be perceived as official co-optation or manipulation (Room 1997). Thus, there is considerable question about the extent to which such movements can or should become an instrument of government prevention policies.

Evidence on effectiveness

In the short term, movements of religious or cultural revival can be highly effective in reducing levels of drinking and of alcohol-related problems. Alcohol consumption in the United States fell by about half in the first flush of temperance enthusiasm in 1830–1845 (Moore and Gerstein 1981). Rates of serious crime are reported to have fallen for a while to a fraction of their previous level in Ireland in the wake of Father Mathew's temperance crusade (Room 1983). The enthusiasm that sustains such movements tends to decay over time, although they often leave behind new customs and institutions of much longer duration. For instance, although the days when the historic temperance movement in English-speaking societies was strong are long gone, the movement had the long-lasting effect of largely removing drinking from the workplace in these societies.

Particularly in the developing world, religious or cultural renewal movements oriented to reducing or prohibiting drinking are often a strong avenue of preventive action (Room et al. 2002). A reform movement among poor indigenous people in a region of Ecuador touched off in 1987 by religious renewal movements and an earthquake appears to have had lasting effects on popular sobriety (Butler 2006).

Treatment and other help

Providing effective treatment or other help for drinkers who find they cannot control their drinking can be regarded as an obligation of a just and humane society. The help can take several forms: a specific treatment system for alcohol problems, professional help in general health or welfare systems, or non-professional assistance in mutual-help movements. To the extent such help is effective, it is also a means of preventing or reducing future alcohol-related problems in the person helped, although its effectiveness at a population level is less clear.

Treatments for alcohol problems need not be complex or expensive. The evaluation literature suggests that brief outpatient interventions aimed at changing cognitions and behaviour around drinking are as effective in most circumstances as longer and more intensive treatment (Finney and Monahan 1998; Long et al. 1998). Positive results from such interventions in primary health-care settings were shown in a WHO study that included a number of countries (Babor et al. 1994).

Evidence on effectiveness

In terms of the effects of treatment on those who come for it, there is good evidence on the effectiveness of treatment for alcohol problems. Typically, the improvement rate from a single episode of treatment is about 20 per cent higher than the no-treatment condition: further treatment episodes are often needed. Brief treatment interventions or mutual-help approaches usually result in net savings in social and health costs associated with the heavy drinker (at least where healthcare is not self-paid), as well as improving the quality of life (Holder and Cunningham 1992; Holder et al. 1992).

The effectiveness of providing treatment as a strategy for reducing rates of alcohol problems in a society is more equivocal. In a North American context, it has been argued that the steep increase in alcohol problems treatment provision and mutual-help group membership in recent decades contributed to reducing alcohol problems rates (Smart and Mann 1990). But the strength of the evidence for this contention is disputed (Holder 1997; Smart and Mann 1997). A treatment system for alcohol problems is an important part of an integrated national alcohol policy, but as an instrument of prevention—of reducing societal rates of alcohol problems—it is unlikely to be very cost-effective (Chisholm et al. 2004).

Building integrated alcohol policies

Alcohol policy at a community or societal level

Often, the different strategies for preventing alcohol problems appear to be synergistic in their effects (DeJong and Hingson 1998). For instance, controls on availability are more likely to be adopted, continued, and respected when the public has been successfully persuaded of their effects and effectiveness. But strategies can also work at cross-purposes: a prohibition policy, for instance, makes it difficult to pursue measures that insulate drinking from harm.

In a society where alcohol is a regular item of consumption, in view of the resulting rates of alcohol-related social and health problems, there is a strong justification for adopting a comprehensive policy concerning alcohol, taking into account production, marketing, and consumption, and the prevention and treatment of alcohol-related problems. In recent years, the idea that there

should be an integrated alcohol policy at community or national levels, reaching across the many sectors of government and civil society that deal with alcohol issues, has become a common public health aim, although accomplishing this has often proved difficult (Smart and Mann 1997; Crombie et al. 2007; WHO 2011).

In terms of strategies we have reviewed for managing and reducing the rates of alcohol problems in the society, there is a clear evidence for effectiveness and cost-effectiveness of measures regulating the availability and conditions of use, and for some of the measures which insulate use from harm. With respect to some aspects of alcohol problems, notably drinking-driving, deterrence measures also fall in the same category. Despite their perennial popularity, evidence of the effectiveness of education or persuasion and treatment strategies in reducing societal rates of problems is limited at best. Education and treatment are good things for a society and a government to be doing about alcohol problems, but they do not constitute in themselves a public health policy on alcohol (Babor et al. 2010). These strategies will nevertheless be pursued in most societies, and they can best be pursued with attention to using relatively cost-effective methods, and to integrating targets and messages with other aspects of alcohol policy.

Alcohol policy in a global perspective

Apart from lapsed agreements made a century ago among the European colonial powers about control of the spirits trade in Africa (Bruun et al. 1975b), there is little tradition of collaboration on alcohol policy at the international level. It has been largely up to each nation to cope on its own with the serious social and health problems associated with drinking. Although alcohol smuggling has a long history, the nation-state could usually rely on distances and traditional trade barriers to keep alcohol issues largely a matter within its borders, in terms of the supply as well as of the problems.

Since the 1980s, an accelerated rate of economic globalization has been seen, which has increasingly rendered obsolete the assumption that alcohol issues are local issues. This globalization affects alcohol issues in three main ways. The first of these is the influence of a global ideology of free markets. In its sweep, this ideology has caught up and dismantled a variety of market arrangements that served to hold down and to structure alcohol consumption. State and provincial alcohol monopolies in North America were weakened or dismantled (Her et al. 1999). In Eastern Europe and the countries in transition, alcohol monopolies were swept away along with most other governmental intrusions in the market (Moskalewicz 1993). Many of the municipally-run beer halls in Southern African countries were privatized (Jernigan 1997). In line with the general ideology, privatization of alcohol production and distribution has been often suggested, abetted or imposed on developing countries by international development agencies (White and Batia 1998). Where the market is organized in a state licensing system for private interests, free-market ideology has often overridden any concerns about public health risks or community need (Room 2004).

Second, trade agreements, trade dispute mechanisms, and the growth of new sales media have effectively reduced the ability of national and subnational governments to control their local alcohol markets. The influence of trade agreements and trade dispute decisions in breaking down alcohol controls, including control of

price through taxation, has been most fully documented for North America (Room et al. 2006) and Europe (Tigerstedt 1990; Holder et al. 1998), but these mechanisms also operate in the developing world. For instance, average taxes on alcoholic beverages in South Korea were lowered in 2000 as a result of complaints to the World Trade Organization by the European Union and the United States (Kim 2000). In 2010–2012, the European Union and United States, joined by Australia, Canada, and five other countries, have argued that Thailand's proposed warning labels on alcohol bottles would violate trade agreements, a first step towards seeking a trade court judgement (O'Brien 2013).

Third, alcohol production, distribution, and marketing became increasingly globalized (Room et al. 2002; Jernigan 2010). Transnational alcohol companies expanded rapidly into low- and middle-income countries in search of new markets, benefiting from weak policy environments and the sweeping tide of market liberalization. Although most alcoholic beverages are still produced in the country in which they are sold, industrially produced beverages were increasingly produced in plants owned, co-owned, or licensed by multinational firms. To promote increased sales, these firms have been able to transform and step up the marketing techniques used in the national market, bringing to bear all the marketing resources and expertise they have developed in other markets.

In light of these converging trends, there is a growing need for mechanisms to express public health interests in alcohol issues at the international level, both in trade agreements and settlements of trade disputes, and in creating mutual obligations for one nation to back up rather than subvert the alcohol regulations and policies of another.

Ways forward for the public health interest

At international levels

The comparative risk analysis in the WHO's estimation of the global burden of disease (GBD) has underlined the substantial role of alcohol in death and disability, particularly in middle- and high-income countries. There are also substantial harms from drinking to others, and these harms are mostly not included in the GBD frame (Laslett et al. 2011). The high rates of harm reflect not only the levels of use and heavy use of alcohol, but also that current expert evaluations rate it as intrinsically among the most harmful of psychoactive substances that humans use (Nutt et al. 2010).

These findings contrast with the current omission of alcohol from international systems of control of psychoactive substances. International markets in most commonly used psychoactive substances are under strict control under the three drug treaties of 1961, 1971, and 1988. International markets in tobacco are also controlled, though more lightly, under a 2003 Framework Convention. Alcohol is thus unique as a commonly used and problematic psychoactive substance on which there is no current international control agreement. As noted, this has left the path open for international limits to be placed on national and local control policies through trade agreements and disputes (Ziegler, 2009; O'Brien 2013).

Apart from any specific treaty provisions, the lack of a treaty status for alcohol has also had implications for resources devoted

to alcohol issues in intergovernmental agencies. In 2013, the number of posts at such agencies devoted to alcohol issues, almost all at the WHO, was in the single digits. In contrast, the number of posts in intergovernmental agencies devoted to tobacco was in the dozens, and to drugs in the hundreds. The treaty processes also mean that, both for drugs and for tobacco, there are regular meetings of parties to the treaties to review progress and consider further actions.

Symbolically, in the early 2010s there was increased recognition at the international level of the importance of alcohol control in public health. In 2010, The World Health Assembly (WHA) adopted a Global Strategy for the Reduction of Harmful Use of Alcohol (WHO 2010). In 2013, implementing United Nations decisions to put a global focus on preventing and controlling non-communicable diseases, the WHA acted to support a draft action plan (WHO 2013a) and a global monitoring framework (WHO 2013b) which included specific attention to alcohol as one of four main risk factors, although the targets and actions specified for alcohol were much less specific and ambitious than those for other risk factors such as tobacco. However, these actions were not accompanied by increases in resources for implementation concerning alcohol issues.

To remedy the deficit in alcohol control at the international level, there are growing calls for a framework convention on alcohol control to be negotiated under the WHO auspices or otherwise, on the model of the tobacco convention (Anonymous 2007; Room et al. 2008), although the advisability of this path has been contested (Taylor and Dhillon 2013, and commentaries). Another option was briefly discussed at the 2012 WHO Expert Committee on Drug Dependence: scheduling alcohol under one of the United Nations drug conventions. This was referred for consideration at a future Expert Committee meeting (WHO 2012, p. 16). It is clear that alcohol would qualify for scheduling under the treaties' criteria. Scheduling alcohol under a drug treaty would provide de-facto insulation from trade treaty restrictions on control, and indeed provide mechanisms for countries to control imports. Such a step would presumably require amending at least one of the drug treaties to allow for regulated domestic markets for non-medical use of at least some scheduled drugs, but moves in the 2010s towards regulated cannabis markets point anyway toward such a development.

Apart from the sphere of intergovernmental action and agencies, there has also been a deficit in international activity in the sphere of non-governmental organizations (NGOs). At a global level, the main NGOs active have been the Global Alcohol Policy Alliance, the International Council on Alcohol and Addictions and the World Medical Association; at regional levels, there are such bodies as Eurocare and Forut. While the global alcohol industry is well organized to oppose effective alcohol policies, through such organs as the International Center on Alcohol Policy (Bakke and Endal 2010; Casswell 2013), the alcohol area lacks the dense networks of public health-oriented international NGO activity found in fields such as tobacco and drugs.

At national and subnational levels

As outlined earlier, over the last 40 years, a substantial literature has emerged which allows a differentiation of prevention strategies and policies in terms of their effectiveness. Some strategies—for example, school education, public information campaigns, and

provision of alternatives—are often politically popular but have limited or no effect. A few strategies that have proved effective—notably, drinking-driving countermeasures—have been applied in a number of countries. Other effective strategies—especially controls on price and availability—have been widely resisted in the political process, and undercut by trade agreements. Ironically, our knowledge of the effectiveness of availability and price controls has often come from studies made possible by the fact that the stricter controls of the past were being dismantled (Olsson et al. 2002).

From the perspective of promoting public health, the lessons of this literature need to be applied. We now have much better evidence than formerly of the scope and distribution of the problems. We have a literature on policy impacts with good information on cost-effectiveness. The need is to focus policy attention, and to build public support for action. A wide range of government departments are responsible for the diversity of problems due to drinking. Police and justice agencies deal with drink-driving and with alcohol-related violence; welfare departments and agencies deal with family problems and immiseration when a parent drinks heavily; hospitals and health services deal with sickness and injury due to drinking. Typically, different levels of government each have some responsibility: for instance, taxes may be a national responsibility, hospitals a state or provincial task, welfare a local government task. Efforts to coordinate across departments and levels of government also run up against the issue that the State has mixed interests with respect to alcohol sales (Mäkelä and Viikari 1977), and are often impeded by alcohol not being a major priority for any of the players. Both at national and subnational levels, effective action will require that priorities be set in a situation where responsibilities are often divided and dispersed.

It is clear that, with sufficient political will, the difficulties can be transcended. For instance, in Victoria, Australia, the commitment to drive down the loss of lives—particularly young lives—from traffic crashes drove effective cross-department coordination and a series of policy and enforcement measures—some involving alcohol. Between 1989 and 2004, traffic deaths were halved (Johnston 2006), and they have since fallen further. The steady success of efforts to decrease the proportion of the population smoking cigarettes is another example of a good public health result with concerted action. Just such focused and coordinated attention and action will be required to drive down rates of alcohol-related problems.

Injury prevention and control: the public health approach

Corinne Peek-Asa and Adnan Hyder

Introduction to injury prevention and control

Injuries contribute significantly to premature life lost and years lived with disability for all countries, all regions of the world, and all age groups. According to analyses of the 2010 Global Burden of Disease data, injuries cause over 5 million deaths per year, accounting for nearly 10 per cent of all deaths and more than 11 per cent of disability-adjusted life years (DALYs) (Global Burden of Disease Study 2012). For children under 14 years of age, road traffic crashes, drowning, fires, poisoning, interpersonal violence, and war are all in the leading ten causes of death. Deaths represent just a small proportion of the many injuries that cause serious injury and potentially life-long disability, and injuries also cause significant psychological trauma and financial loss. The burden of traumatic injuries necessitates that injury prevention be considered an international public health priority.

Because the majority of us will suffer multiple minor injuries throughout our lives, most of which cause only minor discomfort or inconvenience, we may be lulled into believing that injuries are just part of life. However, a serious injury or the traumatic death of a loved one can completely change the course of the lives of those affected. The toll of these injuries is also extremely deleterious to families, communities, and societies.

Many injuries can be prevented, and global investment in traumatic injury prevention will have significant long-term health and financial benefits. For developed countries, progress has been made in reducing the toll of traumatic injuries. In the United States, for example, road traffic crashes per million vehicle miles travelled decreased nearly 90 per cent from the 1930s into the twenty-first century (Institute of Medicine 1999). Mortality rates have decreased for deaths from drowning, residential fires, homicide, and poisoning, among others. However, these rates remain unacceptably high knowing that many effective prevention strategies have not yet been widely implemented.

The burden of traumatic injury worldwide is disproportionately concentrated in lower-income countries. The World Health Organization (WHO) anticipates that, if current trends continue, road traffic injuries, interpersonal violence, war, and self-inflicted injuries will all be among the leading 15 causes of DALYs lost by

the year 2020. Road traffic crashes, which in 1990 ranked as the ninth leading cause of DALYs lost, is predicted to reach the rank of three in 2020 (Peden et al. 2002). Operations of war will rise from the rank of 16 in 1990 to eight by 2020, and interpersonal violence will rise from rank 19 to 12. Despite some successes in many areas of injury prevention, new risks, changing environments, and increasing population size constantly challenge injury control efforts.

Effective injury prevention strategies will require organization of the public health response and increased integration of professionals from many backgrounds. Modern injury control research combines ideas and skills from public health, biomechanics, engineering, behavioural sciences, law, law enforcement, medicine, and urban planning, among others. Research that identifies how effective interventions in high-income countries (HICs) can be translated in low- and middle-income settings is a priority, but injury prevention strategies will need to be appropriate for local environments. Injury prevention activities that integrate multiple approaches within an organized public health response have a stronger chance of success.

This chapter will present the current state of knowledge regarding the burden of injuries and will introduce the basic concepts of building injury prevention infrastructure and capacity.

Causal model of injuries

Injuries are generally divided into the two broad categories of intentional and unintentional. Intentional injuries are those in which there was an intent to commit harm, either to oneself or someone else. Unintentional injuries occur without a direct intent to commit harm, even if gross negligence was involved. For example, a motor vehicle occupant death caused by a drunk driver would be considered an unintentional injury even though in many countries the driver could be prosecuted for a crime.

Injuries are further classified by their cause, such as motor vehicle occupant injuries, drowning, suicide/attempted suicide, homicide/assault, or residential fire injuries. Until the late 1990s, cause and intent were coded together, so that, for example, a poisoning death would not be distinguished as intentional or unintentional. In the 1990s, collaboration between the US Centers for

Fig. 9.4.1 Causal model for injuries.

Disease Control and Prevention and the American Public Health Association recommended that cause and intent be considered as separate components of describing an injury, and most data are now coded accordingly (Centers for Disease Control and Prevention 1997). Through this collaboration, a matrix to code injuries by intent and cause using the International Classification of Diseases, 9th revision, was developed. This matrix served as a template to create codes for injury cause and intent that are now included in the 10th revision of this coding system.

Injury causes are very broad and represent a diverse range of physical harm, and thus can be difficult to tie together conceptually. The traditional epidemiological model for infectious diseases provides a framework for the epidemiological study of traumatic injury (Fig. 9.4.1). At the centre of the causal pathway for injuries is the agent–host interaction. The agent, which in the case of injuries is energy, is absorbed by the host to cause injury. Energy can take many forms, such as mechanical, electrical, chemical, radiation, and thermal. An example of an agent–host relationship is a motor vehicle crash, in which the energy exerted on the individual is mechanical. The reservoir is the place in the environment where the agent is found. The potential for energy transfer exists everywhere, but its potential to cause injury is limited to specific conditions. For instance, the potential energy in a motor vehicle exists only when the car is being driven, and causes injury only when the vehicle crashes.

Vehicles and vectors are mechanisms which transport energy from the reservoir to the host. A vehicle is an inanimate object, such as a motor vehicle; a vector is animate, such as a dog biting a child. For many injury causes, vehicles and vectors are both involved in energy transfer, such as when one individual (vector) stabs another with a knife (vehicle). The injury outcome is the trauma or injury sustained by the individual, and is influenced by host responses to the energy. Only energy transmitted beyond a host's tolerance causes an injury, and therefore not all exposures to energy result in noticeable injury. A human has some resistance to energy which can be increased through exercise or protective devices, or reduced through changes in intrinsic factors such as existing medical conditions or age and through extrinsic factors such as fatigue and alcohol.

This causal model is important when considering injury prevention strategies. Injury prevention aims to prevent energy transfer or to reduce the amount of energy that is transferred. Prevention activities can focus on the host, on the environment, on vehicles or vectors, or combine all of these components. A theoretical approach to injury prevention based on this model is presented later in this chapter (see ‘Theoretical basis for injury prevention’).

Injury data sources

Globally, improved data infrastructures and increased access to data has aided in the rising awareness of the burden of injury and violence as a health problem. Data that provide information related to injuries can be found from a wide variety of sources, both within and outside of the health sector (Institute of Medicine, 1999; Hyder and Morrow 2006). Mortality data, most frequently collected through vital statistics reporting, is the most commonly used source for measuring the burden of injury. Most countries have some structure for death reporting that includes the cause of death, although the quality of these data varies markedly around the world.

Efforts to combine global mortality data to compare incidence, years of potential life lost, and DALYs have improved our knowledge of the burden of injury. The Global Burden of Disease study attempted to collect consistent and internationally comparable data (Murray and Lopez 1996; WHO 2002) and is one of the most comprehensive sources of injury mortality data. The data, however, have limitations in reporting and in coding injury types, and thus are an underestimate of overall injuries. The recent Global Burden of Diseases, Injuries, and Risk Factors study is the most comprehensive effort to compare incidence and risk factors for injuries and diseases (Murray et al. 2013). This effort made several key advances in global data comparisons which included expanded and clarified definitions of causes of death, the integration of risk factors and risk behaviours, and improved estimates to reduce uncertainty.

Although these global estimates are extremely valuable for comparisons, they provide little detail about risk factors and circumstances for injuries. Detailed surveillance systems that focus on specific types of fatal injuries have been very helpful to identify and prioritize prevention approaches. For example, the Fatal Accident Reporting System of the US Department of Transportation provides details of road traffic deaths and has helped improve car and road design and has assisted in development and implementation of safety policies. The Census of Fatal Occupational Injuries maintained by the US Bureau of Labor Statistics has helped compare workplace fatalities by occupation and industry and prioritized workplace hazards.

In comparison with mortality data, population-based data of non-fatal injuries and their outcomes are more challenging to collect and far less available, especially in the developing world. In HICs, population-based data describing non-fatal injuries can be found within hospital reporting data, often used to monitor national health indicators. Sources that include injuries as one of many health outcomes often lack detail to inform injury prevention approaches. Other sources are specific to injuries, such as trauma registries. Efforts to pool trauma data, such as the US National Trauma Data Bank or Canadian National Trauma Registry, are helpful in describing larger patient samples, but trauma registries can rarely be tied to a population base. Many data sources outside the health sector cover a wide spectrum of injury-related events, such as data from law enforcement, the transportation sector, criminal and justice sectors, and insurance companies. This diversity of data sources makes the field of injuries and violence unique in terms of the inter-sectoral nature of the information (Norton et al. 2006).

In many instances, data sources can be linked together to provide a more complete description of the injury. Motor vehicle crash injuries, for example, often require data from traffic enforcement to describe the cause and nature of the crash and data from the health sector to describe the injuries and their severity. Linking these data sources can be impeded by issues of privacy and access to identifying information for linkage, as well as data quality issues. In low- and middle-income countries these data systems, if they exist at all, are often not computerized and have never been evaluated for quality, making such linkages even more challenging. However, information from multiple sources is often necessary to examine causal hypotheses about injuries.

A growing emphasis on improving health behaviour has led to global efforts to collect data on risk behaviours. Many countries conduct surveys of health behaviours, such as the US Youth Risk Behavior Survey (Eaton et al. 2012). More recently, multicountry surveys have been launched to compare risk behaviours across countries. One example is the Health Behaviour in School-aged Children study, which surveys adolescents in more than 40 countries (Roberts et al. 2009). These surveys help establish ties between the prevalence of risk behaviours and experiences with injury and violence.

Despite improvements in data infrastructures that have been possible with technological advances, access to high-quality and detailed data on injury and violence remains an important limitation in most countries. Data limitations are particularly problematic in low-income countries. In many low-income countries, death reporting is the only major source of information about the burden of injuries, and these data can have gaps in reporting and coding. The public health infrastructure and routine collection of health information in the developing world has been fragile, especially in regions such as sub-Saharan Africa and South Asia. It is thus not surprising that there has been little tradition of developing specific information sources for injuries. Population-based studies from low- and middle-income countries, though, consistently conclude that the injury burden is higher than reported in

national official statistics and that injuries are significantly under-reported in these regions.

Global burden of injury

According to the 2010 Global Burden of Disease study, over 5 million deaths occur as a result of injuries around the world each year (Table 9.4.1) (Global Burden of Disease Study 2012). More than 25 per cent of these deaths are caused by road traffic injuries (RTIs), with self-inflicted injuries (self-harm) and falls comprising a further 17 and 11 per cent respectively. Likewise, injury death rates are highest for RTIs, followed by self-inflicted injuries and falls; similar patterns are observed for non-fatal health outcomes using DALY rates per 100,000 population (Fig. 9.4.2). Unintentional injuries, including RTIs, falls, drowning, fire burns and poisoning, together result in more than 3.7 million deaths.

RTIs alone kill over 1 million people every year. In 2010, RTIs became the 8th leading cause of death worldwide, up from 10th in 1990—a per cent change of 47 per cent. Males account for more than two-thirds of these deaths. According to the WHO's *Global Status Report on Road Safety*, the majority of those killed are from low- or middle-income countries (LMICs) (WHO 2009). The absolute number of fatalities and the mortality rate resulting from RTIs vary considerably across countries, and although all age groups are affected, young adults, particularly males, are most at risk of loss of life. Since this age group corresponds to the most economically productive segment of the population, RTIs have serious implications for national economies and account for more than 75 million DALYs—some 33 DALYs per 100,000 population.

Falls are the second leading cause of unintentional injury deaths and there were over 540,000 fall-related deaths in 2010. This constitutes a mortality rate of 8 per 100,000 population. More males die from falls than females (approximately 59 per cent and 41 per cent respectively). In addition, falls account for approximately 35 million DALYs or 514 DALYs per 100,000 population.

Table 9.4.1 Deaths from injuries worldwide, 2010

	Total	Females	Males
All injuries	5,073,321 (100%)	1,614,521 (100%)	3,458,800 (100%)
Unintentional injuries	3,715,668 (65.1%)	1,215,865 (75.3%)	2,499,803 (72.3%)
Road traffic injuries	1,328,535 (26.2%)	331,436 (20.5%)	997,100 (28.8%)
Falls	540,499 (9.5%)	221,762 (13.7%)	318,738 (9.2%)
Drowning	349,120 (6.9%)	103,135 (6.4%)	245,986 (7.1%)
(Fire) Burns	337,590 (6.7%)	177,328 (11.0%)	160,262 (4.6%)
Poisoning	180,443 (3.6%)	62,023 (3.8%)	118,420 (3.4%)
Other unintentional injuries	979,481 (19.3%)	320,181 (19.8%)	659,297 (19.1%)
Intentional injuries	1,357,653 (26.8%)	398,656 (24.7%)	958,997 (27.7%)
Self-harm	883,715 (17.4%)	304,634 (18.9%)	579,081 (16.7%)
Interpersonal violence	456,268 (9.0%)	87,828 (5.4%)	368,440 (10.7%)
Other intentional injuries	17,670 (0.3%)	6194 (0.4%)	11,476 (0.3%)

Drowning and fire burns are also significant causes of fatal injury—contributing 9.3 per cent and 9.1 per cent to the global burden of unintentional injury deaths respectively. Drowning accounts for nearly 350,000 deaths in 2010—more than 64,000 of these drowning deaths were among children aged 1–4 years old. Males comprise the majority (70 per cent) of drowning deaths irrespective of age group. The mortality rate from drowning is approximately 5 per 100,000. Non-fatal drowning events result in more than 19 million DALYs lost per year.

Well over 330,000 deaths in 2010 were caused by fire burns, which result in more than 19 million DALYs—287 DALYs per 100,000. However, unlike other injuries, more females than males die from fire burns (compare 53 per cent and 47 per cent respectively). In 2010, more than 180,000 fatal poisonings were estimated, which correlates to a mortality rate of nearly 3 per 100,000 population. Other unintentional injuries including unintentional exposure to firearms, and non-venomous animal contact, that is, bites or attack, among others contributed 19 per cent of the global burden of injuries and result in nearly 980,000 deaths worldwide.

In 1990 self-harm ranked 14th in the top 25 causes of worldwide deaths; and in 2010, it also ranked 13th and is the second leading cause of injury death after RTIs, and the leading cause of intentional injury deaths. Self-inflicted injuries, including suicides, attempted suicide, self-destructive behaviours, and self-mutilation, cause the deaths of over 880,000 people globally, resulting in more than 36 million DALYs lost. Self-harm or self-inflicted injury deaths peak in the 20–24 age group and more than 65 per cent of self-inflicted injury deaths in 2010 were among males. Although self-harm ranks 21st on the top 25 causes of death among females, it ranks 9th in the Caribbean and 10th in East Asian regions. On the other hand, self-harm mortality rates among females are highest in South Asia and Asia Pacific (16.5 and 15.3 per 100,000 population respectively).

Interpersonal violence, including assault by firearm, sharp objects or other means, causes more than 450,000 deaths worldwide; and females account for less than 20 per cent of these deaths. The mortality rate due to interpersonal violence among both sexes is approximately 7 per 100,000 population. However, the extent to which intimate partner violence (IPV) is accurately reported as interpersonal violence is unknown given varying cultural norms and reporting tendencies around the world. For example, a case of apparent self-immolation may in fact be domestic

violence involving fire. Women in countries who have conducted programmes to screen and respond to intimate partner violence, including victim's assistance programmes and social marketing campaigns against intimate partner violence, may be less inhibited to divulge their experiences with violence. Thus the use of country or regionally specific demographic surveys as a supplement to global aggregate data is essential to determine the actual burden.

War or 'collective violence and legal intervention', was estimated to cause more than 17,000 deaths worldwide in 2010, almost two-thirds of which are males (65 per cent). War results in some 960,000 DALYs lost.

Economic and societal burden

The average annual cost of road traffic crashes has been estimated at about 1 per cent of the gross national product in developing countries, 1.5 per cent in countries in economic transition, and 2 per cent in highly motorized countries. The annual economic cost of road traffic injuries globally is about US\$518 billion (Jacobs et al. 2000). In low- and middle-income countries, the annual cost of road traffic crashes is about US\$65 billion, exceeding the total annual amount received by these countries in development assistance. Policies that reduce deaths and injuries from RTIs can save millions of dollars regardless of the income or development level of the country.

Studies exploring the economic and social costs of road traffic injuries in low-income countries show that males who provided the majority of the household income in India and Bangladesh were the most common victims of road traffic fatalities and the consequences included reduced household income and reduced food consumption for the victim's family (Aeron-Thomas et al. 2004). In addition, the poor were found to spend a much greater proportion of their income on funeral and/or medical costs than the non-poor. A recent qualitative study of the intangible costs of RTIs in Mexico acknowledges similar findings but also emphasizes the loss of a family member to RTI can impact not only a family's household economy, but the very stability of the familial unit—in whichever form—as well as the individual family member's sense of her or his life's purpose (Pérez-Núñez et al. 2012).

Estimates of the cost of violence in the United States reach over 3 per cent of the gross domestic product. In England and Wales, the total costs from violence amount to an estimated US\$40

billion annually. The economic effects of interpersonal violence are expected to be more severe in poorer countries, and yet, there is a scarcity of studies on the costs of violence in low- and middle-income countries (WHO 2004). However, estimates from low- and middle-income countries indicate that the overall costs of violence are substantial, ranging up to 25 per cent of annual gross domestic product. Comparisons with HICs are complicated by the fact that economic losses related to productivity tend to be undervalued in lower-income countries. For example, child abuse results in US\$94 billion in annual costs to the US economy (1 per cent of GDP) and intimate partner violence costs the US economy nearly US\$13 billion (0.1 per cent of GDP); this can be compared to 1.6 per cent of GDP in Nicaragua and 2 per cent of GDP in Chile. The cost of gun violence also has been calculated at US\$155 billion annually in the United States.

Theoretical basis for injury prevention

The causal model for injuries allows the injury process to be categorized into distinct phases which are important for prevention (Haddon 1970, 1972). The *pre-injury* phase is the period prior to the energy transfer, the *injury* phase is the often millisecond period in which the energy is transferred to the host, and the *post-injury* phase is the period of recovery and rehabilitation. Prevention approaches affect the injury process in one of these three injury phases.

Primary injury prevention includes prevention strategies that aim to prevent the transfer of injury to the host, and thus act in the pre-injury phase. Examples of successful primary prevention strategies include roadway designs that reduce motor vehicle collisions, child-resistant caps on medication bottles to prevent ingestion and poisoning, and pool fences to prevent submersion and drowning (Graham 1993; Thompson and Rivara 2000).

Secondary injury prevention includes strategies that reduce the amount of energy that is transferred to the host. While these strategies are often put in place long before the injury event, their function acts to reduce energy transferred during the injury phase. Examples of secondary prevention strategies include seat belts and air bags (Evans 1995), motorcycle and bicycle helmets (US General

Accounting Office 1991; Thomas et al. 1994). Seat belts and helmets do not prevent the crash itself, but they reduce the amount of energy transmitted to the host during the crash. Secondary prevention strategies might not prevent injury completely. For example, lower extremity injuries are not prevented by either seat belts or helmets. However, studies have consistently shown that when these devices are present, the risk for mortal injury is much less and injury severity is reduced.

Tertiary prevention strategies act in the post-injury phase to help with recovery and rehabilitation once an injury has occurred. One example is the development of trauma systems, which help with triage and transport of an injured individual to reduce the time between injury and definitive medical care (Mann et al. 1999; Nathens et al. 2000). Optimizing resources to enable recovery and rehabilitation does not prevent the injury or reduce the amount of energy transfer, but tertiary prevention strategies can have enormous impact on improving survival, function and quality of life following an injury.

The Haddon matrix is a framework that combines these injury phases with the major components of the injury causal model to help identify prevention approaches (Table 9.4.2). This matrix, developed by Dr William Haddon in the United States, was the foundation for the study of motor vehicle crashes and countermeasures for highway safety and continues to be an applicable theoretical framework for injury prevention (Haddon 1972). Using the three injury phases, Haddon categorized prevention approaches into those that affect the host, vehicles and vectors, the physical environment, and the sociocultural environment. An example of the Haddon matrix with examples from motor vehicle occupant protection is included in Table 9.4.2.

The Haddon matrix provides a framework for identifying individual approaches to injury prevention. However, one single intervention strategy is unlikely to be highly effective. Multiple collaborative approaches need to be combined to maximize success. For example, the success of seat belt use in reducing motor vehicle occupant fatalities in the United States required a combination of engineering, education, policy, and enforcement that led to the current use rate of 80 per cent (National Highway Traffic Safety Administration 2007). Although seat belts were developed

Table 9.4.2 The Haddon matrix (illustrative)

Phases	Factors			
	Human	Vehicle	Physical environment	Sociocultural environment
Pre-injury	Reduce alcohol intoxication, programmes to increase defensive driving and decrease road rage	Increase vehicle stability, increased visibility	Improvements in road structure and traffic controls, traffic calming measures	Support safety programmes and increase consumer awareness of safety issues
Injury	Use of seat belts and car seats, proper placement of car seats, booster seats	Increase energy absorbed by the vehicle frame, safety features such as air bags, head rests, shatterproof windshields, and collapsible steering columns	Install energy-absorbing guard rails	Programmes to provide car seats, educational programmes about car seat installation and placement
Post-injury	Stabilize serious injuries, reduce bleeding and other complications	Design for easier extrication	Enhanced emergency medical systems and field care	Support infrastructure of trauma care, including 911 system, emergency and trauma care, and rehabilitation services

and available from the early 1900s, they were not required to be a standard feature on passenger cars in the United States until 1968. The steps to getting seat belts installed as a regular feature in passenger cars required considerable advocacy and policy initiatives. However, once the seat belts were installed, use rates without any occupant incentive or education were about 11 per cent. Efforts in the areas of legislation, enforcement, and public education were necessary to achieve the high use rates currently observed. Stricter legislation, for example, is associated with higher use, as evidenced by the higher use rates consistently observed among states with primary (not wearing a seat belt is by itself a citable offence) compared with secondary (not wearing a seat belt can be cited only along with another citation) laws in the United States (National Highway Traffic Safety Administration 2007).

Risk factors for injuries

The social–ecological model is helpful in conceptualizing the relationship of injury risk factors and also the level at which different types of prevention strategies work. The most common social–ecological model used in injury prevention includes four levels: individual, relationship, community, and societal (Fig. 9.4.3) (Dahlberg and Krug 2002; Centers for Disease Control and Prevention 2009). This model posits that individual behaviour is largely determined by the influence of interpersonal relationships, community norms, and societal factors such as culture and political influence.

Individual-level variables that influence injury risk include age, gender, socioeconomic status, health status, and personality characteristics such as risk tolerance and the practice of safety behaviours. Many examples of the influence of individual-level characteristics on injury risk have been documented. For example, men have higher rates of injury than women for almost all causes of injury, and this difference is found consistently across the world. However, women appear to be at greater risk of fire-related burn injuries compared with men, and burn-related injuries account for a much higher proportion of injuries in young children when compared with other age groups (Jie and Ren 1992; Liu et al. 1998). Individual characteristics have been widely

documented to influence the risk for motor vehicle-related deaths. Driver speeding, drinking, distraction, and drowsiness have been identified almost universally around the world as risk factors (Liu et al. 2003; WHO 2004). Declining resiliency and poor health status is an important individual risk factor for injuries among the elderly, particularly falls (Carpenter et al. 2009). Low bone density, poor nutritional status, low body mass index, low calcium intake, co-morbid conditions (hypertension, diabetes), poor performance in activities of daily living, poor cognitive function, poor vision, environmental factors affecting balance, family history of hip fracture, and alcohol consumption have all been identified as individual characteristics associated with increased fall risk (Cummings et al. 1995; Dargent-Molina et al. 1996; Clark et al. 1998; Boonyaratavej et al. 2001). Individual-level interventions often focus on increasing knowledge and encouraging behaviour change.

Relationship-level factors that predict injury include family and interpersonal relationship influences, including the environment in which these relationships occur. Interpersonal relationship factors can increase or decrease risk for injury. For children, parents are a key factor in safety. Limited adult supervision has been associated with pedestrian, drowning and poisoning injury risk in young children (Azizi et al. 1993; Soori, 2001; Brenner 2003; Chadbunchachai et al. 2012). Parent communication style has been tied to risky driving attitudes of teens, and parent driving may influence the driving behaviour of their children (Yang et al. 2013). As we mature, peers and long-term partners become strong influences. The home environment can also influence injury risk. Low socioeconomic status, poor home conditions, and failure to remove home hazards are all factors associated with high and differential rates of home injury (Edelman 2007; Nyberg et al. 2012). Relationship-level interventions often focus on influential communication or changes in the home environment.

Community factors include schools, workplaces, neighbourhoods, all of which are influenced by community social norms and environments. Globally, community factors and characteristics vary more than individual characteristics. For example, the majority of drowning incidents in HICs are associated with recreational or occupational activities, while in most low- and middle-income countries they are associated with everyday activities near natural bodies of water (Kobusingye et al. 2001; Brenner 2003; Hyder et al. 2008). Rural and urban environments also have distinct and different patterns of injury, with injury rates from such causes as road traffic, drowning, poisoning, and occupational-related causes higher in rural communities (Peek-Asa et al. 2004). Prevention strategies usually are designed to impact the climate, processes, and policies in a given local community.

Societal factors encompass the cultural norms and socio-political characteristics that influence safety specifically, such as the safety culture. Broad social factors such as population health, socioeconomic status, and political stability also influence injury risk (Centers for Disease Control and Prevention 2009). For example, injury death rates are far higher in low-income countries when compared to HICs. For road traffic deaths, motorization rates rise with income (Kopits and Cropper 2003). In HICs, high motorization rates are not strongly correlated with road traffic deaths (Graham 1993). However, a growing number of LMICs that are experiencing very rapid increases in motorization have had a disproportionate increase in road traffic fatality rates

(Eds.), *World Report on Violence and Health*, World Health Organization, Geneva, Switzerland, Copyright © 2002, available from http://www.who.int/violence_injury_prevention/violence/world_report/en/.

(Ghaffar et al. 1999). Much of this increase is due to the lack of an organized safety culture, lack of road traffic safety laws and their enforcement, and governing agencies not prioritizing road safety. Prevention strategies at the societal level often focus on policy implementation and enforcement as well as efforts to change social norms.

Successful injury prevention strategies

Reducing the burden of injury requires multifaceted and comprehensive efforts. As demonstrated through the Haddon matrix and the social-ecological model, injuries occur as a complex interplay between individuals and their physical and sociocultural environments. Injury rates have very clear patterns and determinants that are affected by individual, family, community, geographic, and sociocultural factors. These factors and their interplay must be understood for effective intervention and prevention. Although individual, one-time programmes can have impact by increasing knowledge, encouraging behaviour change, or modifying an environment, long-term and sustainable reductions in injury usually require changes at the sociocultural level.

As the evidence base of successful injury prevention and intervention strategies increases, so do opportunities to translate these programmes to new populations. Translational research, both at the clinic and community level, is a promising priority for injury prevention. Considerations for translation of programmes to new populations include the priority of the injury problem in the new population; human and economic resources to implement and sustain the programme; and cultural relevance of the programme (Woolf 2008). Injury prevention research, which tends to have a relatively short period between action and measurable impact, will likely gain in priority as nations realign research investments to focus on high-impact projects (Zerhouni 2005).

Resources to identify successful injury prevention programmes

A growing evidence base helps guide decisions on the most effective injury prevention strategies. In addition to information to measure the scope, burden, and cost of injuries, several good

resources are available to identify evidence-based injury prevention approaches (see Table 9.4.3).

Cochrane Collaboration

The Cochrane Collaboration provides scientific evidence-based reviews of healthcare interventions through the Cochrane Library (Bero and Rennie 1995; Higgins and Green 2011). The Cochrane Library now houses more than 6,000 systematic reviews and more than 8,500 study protocols. This includes more than 500 reviews on injury prevention topics. Abstracts are available free of charge and full reviews are available by subscription, with most major libraries holding subscriptions (see Table 9.4.3). Cochrane reviews are highly weighted towards evidence from randomized controlled trials, which excludes many of the observational evaluations conducted for injury interventions. The search strategy protocol requires inclusion of international findings as well as unpublished data, and when sufficient data are present meta-analyses are conducted. Thus, these reviews are meant to be applicable to an international audience. Recent additions on injury prevention include home safety education, alcohol interventions, and a synthesis of evaluations of the WHO Safe Communities programme (Spinks et al., 2009; Kendrick et al. 2012; Muckle et al. 2012).

Campbell Collaboration

The Campbell Collaboration, begun in 1999, includes systematic reviews of social intervention, divided into the categories of education, crime and justice, international development, and social welfare (Davies and Boruch 2001). The goal of the collaboration is to provide evidence for policy decisions regarding social issues. While the majority of injury prevention-related reviews are found within the crime and justice reviews, many reviews in the other categories are strongly related to injury and violence prevention. The Campbell Collaboration includes evidence from all types of study designs, and has methods groups to ensure systematic interpretation of findings. Recent injury-related reviews address court-mandated interventions for domestic violence, interventions to reduce distress among victims of violence, and school-based bullying prevention programmes (Farrington et al. 2008; Feder et al. 2008; Regehr et al. 2013).

The Guide to Community Preventive Services: Systematic Reviews and Evidence-Based Recommendations (the *Guide*) was developed by the Task Force on Community Preventive Services, established by the United States Centers for Disease Control and Prevention (Pappaioanou and Evans 1998). The *Guide's* recommendations are primarily based on evidence of effectiveness, including the suitability of the study design, but they also assess the applicability of the intervention to other populations or settings, the economic impact, barriers observed in implementing the interventions, and if the intervention had other beneficial or harmful effects (Briss et al. 2000). The *Guide* then provides a recommendation as to whether the approach is 'strongly recommended', 'recommended', has 'insufficient evidence', or is 'discouraged'. The *Guide* has injury-related reviews in the categories of alcohol, motor vehicle, physical activity, substance abuse, worksite, mental health, social environment, and violence (see Table 9.4.3).

Many global sources of information provide guidance on a variety of injury issues. The National Center for Injury Prevention and Control in the United States provides information about many injury prevention programmes and includes WISQARS, an injury and violence data query tool (see Table 9.4.3). The Department of Violence and Injuries Prevention of the WHO offers a diversity of guidelines and manuals that provide assistance in implementing programmes or conducting research. Examples include guidelines for establishing injury surveillance systems, conducting community based surveys and evaluating pre-hospital care. International non-governmental organizations also offer a variety of assistance and expert members on specific issues (see Table 9.4.3). Examples include the Society for the Advancement of Violence and Injury Research, the Safe States Alliance, the International Society for Child and Adolescent Injury Prevention, the Road Traffic Injuries Research Network, and the International Society for Violence and Injuries Prevention (for website details see Table 9.4.3).

Examples of injury prevention approaches

Successful injury prevention strategies: road traffic injuries

With increased knowledge about the burden of road traffic injuries globally there is growing attention to making roadways safer. Over the last several decades, many high-income countries have experienced decreases in motor vehicle occupant death rates, even while the total miles driven, and thus exposure to the roadway, have increased. In contrast, middle- and low-income countries have experienced large increases in road traffic fatality rates. Nearly 90 per cent of road traffic deaths now occur in low- or middle-income countries, although these countries have only 48 per cent of the world's registered vehicles (WHO 2009). Worldwide, almost half of road traffic deaths are among pedestrians, cyclists, and riders of two-wheeled vehicles. As the fleet of vehicles on these roadways gets more complicated, especially with a growing number of passenger and industrial vehicles, there is potential for continued increases in fatality rates. Efforts to reduce road traffic injuries throughout the world are a good case study of how an integrated approach can lead to successful prevention.

The main reason for success in HICs has been a comprehensive approach to intervention that has included integration of environmental, engineering, legislative, and educational approaches. These changes have evolved over decades, leading to

the development of a safety culture around road traffic. A 'culture of safety' exists when safety is embraced as a fundamental goal at multiple levels: government, community, and individual. The paradigm shift to a traffic safety culture was first formalized in 1997 by the Swedish government with their Vision Zero Initiative (n.d.). Since then, many other countries have adopted similar initiatives which include a traffic safety culture as the foundation.

Historically, as the number of passenger vehicles increased with industrialization, many high-income countries focused efforts on protecting vehicle occupants, and these efforts have shown many successes. In the United States, The National Highway Traffic Safety Administration and the Federal Highway Safety Administration estimate that 243,000 lives were saved between 1966 and 1990 as a result of highway, traffic, and motor vehicle safety programmes (Institute of Medicine 1999). Road modifications mandated by the Federal Highway Traffic Safety Act of 1966 led to safer roadway infrastructures which allowed more cars to travel at higher speeds while reducing crash risk (Graham 1993). At the same time, changes to the motor vehicle itself increased the likelihood of survival in a crash. In addition to the implementation of seat belts and then air bags, legislation required modifications that improved vehicle crash worthiness. Some examples of these modifications include shatter-resistant windshields, collapsible steering columns, crash-friendly dashboard surfaces, frames that are resistant to passenger space intrusion, increased strength of the vehicle frame, seat, and doors, lap and shoulder belts, and air bags (Haddon and Baker 1981). Studies have found that these safety improvements to the motor vehicle led to a 24–40 per cent decrease in fatal crashes and saved over 9000 lives each year (Robertson 1981; Institute of Medicine 1999).

Most of these changes were due in part to legislative efforts, and these efforts were themselves multifaceted in nature. For example, the implementation of many of these laws required a successful engineering development as a foundation—improved crash worthiness of cars was based on concentrated research to identify the most successful design features, which were then required legislatively. Other legislative approaches are more behavioural in nature, such as laws that require seat belt use, driver training, speed limits, and laws that aim to reduce drunk driving. Implementation of these laws requires successful advocacy and education of legislators. However, their effectiveness varies dramatically. For example, most countries have laws against drinking and driving, yet countries have wide variation in the rate of alcohol-involved crashes as well as the number of drinking drivers, drivers cited for drinking and driving, and punished for drinking and driving. While this variation has much to do with factors associated with patterns of alcohol consumption, access to transportation, and the driving culture, this variation is also due to factors associated with the laws themselves. The effectiveness of legislative approaches depends on the level of enforcement that accompanies them and on the perception that the legislated consequences will actually occur (Mann et al. 2003). For example, the effectiveness of drinking and driving laws is influenced by the level of enforcement, the ability of courts to impose penalties, and that the nature of the penalties serves as a deterrent.

The focus on motor vehicle occupants without concomitant integration of urban planning, sustainable transportation, and pedestrian and bicycle safety may be problematic in the long run. More recently, countries throughout Europe as well as Australia

and the United States have introduced an approach called ‘traffic calming’ that aims to control motor vehicle traffic and speed in neighbourhoods, and thus increase safety and walkability in communities (Ewing 1999). The concept of traffic calming dates back to the Dutch city of Delft in the 1960s, when residents angry with fast-moving cars cutting through their local streets blocked them with gardens, social areas, and playgrounds (Ewing 1999). Modern traffic calming involves a variety of approaches to reduce traffic volume and speed in residential areas using visually appealing strategies.

Success in reducing road traffic deaths has depended on the development of an infrastructure that can identify and respond to road hazards, and a wide variety of approaches to address these hazards. In some developed and many developing countries, the car culture is growing without concomitant safety cultures (Bishai et al. 2003; WHO 2007). Highway design standards are often outdated or translated too directly from an industrialized country, and insufficient resources for roadway maintenance are available (Transport and Road Research Laboratory 1991). Poorly designed and maintained roadways are even further stressed by an ever-increased number and variety of vehicles. In addition to a growing number of passenger cars and a high proportion of commercial vehicles and buses, developing countries’ roadways include animal-powered vehicles, small engine vehicles (such as scooters and motorcycles) that carry multiple people, bicycles, human-powered transport vehicles (such as rickshaws), and pedestrians. This complex mix of vehicles contributes to increased deaths on the road.

In order to avert the growing toll of road traffic deaths, the WHO has called for a ‘systems approach’ in which the interaction between vehicles, roads, road users and their physical, social, and economic environments form the basis for a multisectoral response (WHO 2004). The implementation of comprehensive traffic safety laws has been identified as one of the most important actions to reduce global road traffic injuries, and these laws must include enforcement with appropriate penalties and concomitant public awareness campaigns. The WHO has also called on governments to identify lead agencies in traffic safety, and to give these agencies a clear mission and authority for creating safer roads. Governments must also encourage multisectoral collaboration and support ongoing collection of data. These steps all fit within defined models of creating a global traffic safety culture.

Successful injury prevention strategies: drowning

Drowning prevention efforts often focus on three types of strategies: (1) remove, reduce, or change the water hazard; (2) change behaviour in risk-taking, supervision, or skills around water; and (3) prevent contact between people and the water environment (Wilson and Rogmans 2006). While these strategies remain relevant in all settings, drowning is experienced differently in HIC and LMIC settings. In HICs drowning events are often associated with recreational swimming, in swimming pools or along the coast; while drowning in LMICs often occurs as a result of everyday activities near open bodies of water, ditches, or uncovered wells (Hyder et al. 2008). Therefore, successful drowning prevention strategies are often not transferable from HICs to LMICs.

Since the 1970s, HICs have implemented well-established preventive measures to prevent drowning events

including: mandating fencing and self-closing or self-latching gates around domestic and public swimming pools; requiring supervision by certified lifeguards at public pools and swimming beaches; and recommending the use of personal flotation devices for boaters and novice swimmers (Thompson and Rivara 1998; Pearn et al. 2008; Centers for Disease Control and Prevention, 2012). For adults, basic swimming instruction is an important skill, and deters the likelihood of drowning particularly in domestic or public swimming pools. A recent evaluation of a rip current related intervention in Australia revealed intervention area respondents were more likely to report they would never swim at an unguarded beach, and if caught in a rip would: signal a guard, not swim directly to the beach against the rip, and float and drift with the rip (Hatfield et al. 2011). The knowledge of basic life support or resuscitative measures, that is, cardiopulmonary resuscitation, among non-medical personnel is also crucial to treat drowning victims. Likewise, alcohol is an important risk factor for drowning that ought to be avoided whether at swimming pools, at swimming beaches or on watercrafts including recreational boats.

Many of these drowning prevention strategies are applicable to children though swim instruction thus far has been understudied and has yielded limited effectiveness (Asher et al. 1995). Attentive supervision of children in and around domestic swimming pools, swimming beaches and around the home is crucial. And yet, a recent Cochrane review of home interventions found there was a lack of evidence that home safety interventions were effective in preventing children being left alone in the bath, which is a common cause of drowning among children (Kendrick et al. 2012).

In LMICs, the epidemiology of drowning is quite different as children comprise the largest burden. In Bangladesh, for example, drowning is one of the most common causes of death in children aged 1–4 years (Borse et al. 2011). More importantly, the critical risk factor—water—abounds; a single district alone might have 50,000 or more ditches and ponds. Obviously, fencing off these bodies of water is not feasible in this context; however, other barrier-based interventions for drowning prevention in children younger than 5 years have been piloted in rural Bangladesh (Callaghan et al. 2010). Door barriers (which prevent young children from leaving the home) and playpens (which limit movement of young children) appear to work in pilot settings, especially for children aged 1–3 years at high risk of drowning when their mothers are busy performing their daily household tasks. In addition, crèches (day care centres) have also shown promise by removing children from high-risk contexts during the highest risk time of day in similar settings (Rahman et al. 2010). These interventions might be effective ways to reduce the number of drowning events and to ease the burden of supervision on mothers. Producing such barriers in the community or making them available at little or no cost to low-income families in LMICs, particularly in regions where drowning is most endemic, is an important agenda for global public health. However, large-scale studies are needed to determine the true effectiveness of these interventions before they can be widely recommended.

Successful injury prevention strategies: burns

There are sufficient data available from HICs to support the claim that burns can be successfully prevented using education,

engineering changes, enforcement of legislative protection, and environmental modifications (Peck et al. 2009). A range of successful burn prevention strategies such as smoke detectors, regulating hot water heater temperatures, mandating flame-resistant children's sleepwear, and enforcing safe and proper electrical wiring of residences and businesses have been implemented across HICs (Mock et al. 2008). Installing smoke detectors in the United States, for example, has been associated with a 61 per cent reduction in the risk of death from residential house fires (Marshall et al. 1998). This reduction has been made possible by programmes such as the Smoke Alarm Installation and Fire Safety Education of the National Center for Injury Prevention and Control (part of the Centers for Disease Control and Prevention) which has targeted low-income households since 1998 and has installed approximately 553,000 smoke alarms with 3755 lives potentially saved (Kress et al. 2012). Further, should someone in a HIC suffer a burn, she or he is likely to be transported to a dedicated burn centre in a timely fashion to receive specialized care necessary to reduce damage and restore functioning.

Many of these strategies are impractical for LMICs given certain institutional and environmental challenges and a different epidemiology of burns. For example, childhood burns risk factors include: use of kerosene, cooking in open spaces, overcrowding, and lack of parental supervision (Dissanaike and Rahimi 2009; Mashreky et al. 2010; Van Niekerk et al. 2010). Interventions that have been proposed include separating the cooking area from the living area, increasing the height of cooking surfaces, making separate cooking stations outside the house, reducing the amount of flammable substances available in the household, and enhancing child supervision (WHO 2008).

Two vulnerable groups can be identified in LMICs—young infants and children and adolescent/adult females (Golan et al. in press). For younger children, a partitioned area imposed during cooking hours, shelves at appropriate heights, and supervision to avoid young children carrying hot objects are being suggested. In addition, timely outpatient assessment and treatment is vital to mitigating the impact of such burns, and creation of social awareness has been used for mothers and caretakers (Mukerji et al. 2001). Interventions for the second risk group (young women) include safe, inexpensive and efficient kerosene lamps and stoves placed above the floor level (McLoughlin 1995). Other efforts at encouraging women (through grassroots education and multi-media) to wear appropriate clothing to reduce clothes catching fire and using flame-resistant materials in the manufacturing of local dresses are being explored (Jayaraman et al. 1993).

Some of these interventions have been reiterated by the WHO's world report on child injury prevention which also promotes the use of safe kerosene lamps, separating cooking areas from living areas, raising cooking facilities off the ground, banning of fireworks, and wearing flame-retardant clothing materials (WHO 2008). In LMIC households, cookstoves are commonly used for cooking and heating and unfortunately, poor manufacturing standards, low quality control, and a lack of safety features have made this a key risk factor for burns (Peck et al. 2008). In response, the Global Alliance for Clean Cookstoves, led by the United Nations Foundation, seeks to encourage 100 million homes in LMICs to adopt clean and safe cookstoves by 2020 as well as support a clean and innovative cookstove industry. Such cookstoves will dramatically reduce fuel consumption, exposure to harmful

emissions and smoke, and the risk of fire burns (Global Alliance for Clean Cookstoves n.d.).

Successful injury prevention strategies: acute care

Many injuries lead to death because of inadequate emergency and trauma care, and pre-hospital deaths are disproportionately large in LMICs. In low-income countries, pre-hospital mortality is extremely high. For example, one study found that 81 per cent of trauma deaths occurred in the pre-hospital setting in Ghana, a low-income country, compared with 72 per cent for Mexico, a middle-income country, and 59 per cent in the United States (Mock et al. 1998).

Improvements in emergency medical response and trauma care have had a major impact in preventing deaths from injuries. Reducing the time between injury and definitive treatment leads to improved outcomes (Institute of Medicine 1999). The most effective way to reduce time to treatment is through the implementation of a trauma system, with changes in the social environment to include better coordination between agencies, triage and transport protocols, assignment of treatment levels to trauma centres, and improved training and certification at all levels of emergency care delivery.

Early evaluations of trauma systems conducted in high-income countries focused on the number of deaths that could be prevented, and estimates were in the range of 20 per cent to 40 per cent (Shackford et al. 1986; Mackenzie et al. 1992; Mullins et al. 1994). One meta-analysis of the effectiveness of pre-hospital trauma systems in LMICs concluded that injury mortality could be reduced by approximately a quarter (Henry and Reingold 2012). Effects were strongest for middle-income countries, largely because they had stronger health infrastructures on which to build trauma systems. One study estimated that if injury case fatality rates in LMICs could be reduced to the same level as those in HICs, more than 1.7 million deaths, over a third of all injury deaths, could be reduced globally (Mock et al. 2012).

Developing systems for coordinated care, especially when out-of-hospital coordination is involved, is a challenge. In many countries, no organized system to identify and transport patients to the hospital exist (Nielsen et al. 2012). In low-income countries and in rural areas, patients are more likely to arrive at the hospital in private vehicles than in an ambulance (Young et al. 2003; Nielsen et al. 2012). The private citizens who provide emergency transport are also the most likely to provide first aid in the absence of trained emergency response personnel. Because building emergency transportation infrastructures would be expensive, experts have proposed formalizing relationships with commercial vehicles and local citizens to create an organized approach (Mock et al. 2012).

Lack of trained specialists in emergency care, both in the field and in hospitals, is another barrier to reducing trauma death. Many countries lack trained medical personnel, equipment, and infrastructure (Kobusingye et al. 2005). An evaluation of trauma care capabilities in Mexico, Vietnam, India, and Ghana indicated that even when a sufficient number of healthcare professionals were trained, 'brain drain' from rural to urban and from low- to higher-income communities led to widespread provider shortages (Mock et al. 2006). In order to develop a stronger trauma response system, improvements must be made in the areas of increased human resources, physical resources, security for healthcare

personnel, transportation systems to get patients to definitive treatment, and administrative infrastructure (Kobusingye 2005; Mock et al. 2006).

Although many of these improvements require new resources, system-wide changes are possible through effective planning even in the absence of significantly increased resources. For example, several low-cost trauma training programmes have been developed and used effectively in low-income countries, and these have contributed to decreased injury mortality (Kobusingye 2005). Administrative changes, such as making necessary diagnostic equipment available for critical trauma cases, are also low cost. However, identifying and implementing low-cost strategies cycles back to the need for data. Finding the low-cost strategies that will work in a healthcare facility will be enhanced by data systems that can track trends in patient treatment and be used for quality assurance. These systems are lacking in many healthcare organizations throughout the world.

Improving emergency medical systems and trauma treatment capacity could greatly reduce injury mortality worldwide, and also reduce the physical, emotional, and financial consequences of severe injuries. These efforts need to be in collaboration with general worldwide efforts to improve access to public health and medical services. Over the past few years, the WHO has released guidelines for pre-hospital and trauma care with a special focus on LMICs, and approaches to improved acute care are increasingly evaluated in different countries.

Building capacity for injury prevention

In order to identify and implement successful injury prevention strategies, countries, states, and local communities need to develop necessary infrastructure and capacity to conduct the essential activities of an injury prevention programme. Infrastructure includes the designation or creation of agencies and leadership to oversee and integrate essential injury control activities within an inter-sectoral strategic framework. Capacity includes the availability of human, financial, relational, and structural resources. Both components are vital to the sustainability of any injury prevention and control programme. Since there is a lack of trained injury prevention professionals in many LMICs, capacity development efforts are critical in the developing world to address their high burden of injuries and unique challenges.

The WHO Department of Violence and Injury Prevention and Disability has recently responded to this need by outlining three key domains for such efforts in *Capacity Building for Preventing Injury and Violence: Strategic Plan 2009–2013* (WHO Department of Violence and Injury Prevention and Disability 2009). These domains include:

- ◆ Human resources: people and the knowledge and skills they require.
- ◆ Institutional and infrastructural capacity: the systems and structures necessary to allow for effective human resources.
- ◆ Networks and partnerships: a means by which capacities can be strengthened within and across settings (WHO Department of Violence and Injury Prevention and Disability 2009).

In order to facilitate such efforts, the WHO has developed two training programmes, Teach Violence and Injury Prevention (TEACH-VIP) and Mentor Violence and Injury Prevention

(MENTOR-VIP). TEACH-VIP, now in its second iteration, is a comprehensive injury prevention and control curriculum which is delivered via PowerPoint presentations and supplementary information structured around 67 lessons—22 ‘core’ and 45 advanced’ (WHO n.d. a). Whereas the TEACH-VIP training curriculum focuses on the transfer of knowledge, MENTOR-VIP offers an opportunity for junior investigators and injury prevention professionals to further develop key skills. MENTOR-VIP is a 12-month mentorship programme which matches mentees with leading injury prevention experts to accomplish specific goals (WHO n.d. b). In addition to training materials developed by the World Health Organization, many new online training modules are available. One example is the Road Traffic Injury Prevention and Control in Low- and Middle-Income Countries, which provides seven modules to introduce a non-expert audience to road traffic safety principles (<http://www.jhsph.edu/research/centers-and-institutes/johns-hopkins-international-injury-research-unit/training/courses-in-injury-prevention/free-online-training/>). The CDC National Center of Injury Control and Prevention offers several online training programs focused on topics such as the principles of prevention (<http://www.cdc.gov/violenceprevention/POP.html>) and concussion management (<http://www.cdc.gov/violenceprevention/POP.html>).

The development of a critical mass of trained injury professionals within a country or region to understand the local environment, develop, implement, and evaluate appropriate prevention programmes is a crucial step. The Fogarty International Center of the National Institutes of Health in the United States has provided opportunities for twinning between US-based and developing country institutions for capacity development which targets all three WHO domains (Fogarty International Center n.d.). These programmes cover collaborations in countries such as China, Columbia, and Pakistan; topics from traumatic brain injuries, violence, to emergency care; and promote sustainable research and dissemination of results to influence policy and investments in each country.

Conclusion

Despite the high burden of injuries throughout the world, investment in safety and injury prevention infrastructure has been low. In low-income countries such as Pakistan and Uganda, approximately US\$0.07 per capita was devoted to safety. In every country, the amount invested in prevention is far surpassed by the amount spent on the treatment of traumatic injuries, and thus studies that focus on cost benefits are badly needed. International assistance has also not prioritized safety or injury prevention. External assistance to the health sectors of low-income countries was US\$2–3 per DALY lost to infectious diseases, but only US\$0.06 per DALY lost to injuries (Mock et al. 2004).

Since 90 per cent of the world’s population lives in LMICs, and the burden of injuries is predicted to increase in these countries, it is imperative that future research and development activities focus especially on their needs. Basic research to describe the existing burden, causes, and distribution of injuries is still needed in LMICs. Trials of injury interventions have largely not been conducted in LMICs, and there is a great need to modify, adapt and test existing, as well as new interventions in these specific settings. Work is also required to assess barriers to implementation of such interventions globally.

The role of international organizations (such as the WHO and the World Bank) and national agencies (such as ministries of health or medical research councils) needs to be emphasized in moving ahead the injury prevention agenda. The international movements currently underway for violence prevention and road traffic injuries prevention as promulgated through the two WHO world reports are examples of how joint global–national partnerships are needed for making change.

Progress will also be supported if a growing number of professionals become advocates for safety. Professionals from public health, medicine, engineering, social services, urban planning, law and law enforcement, among others, can all have a strong voice in raising awareness for safety programmes and to encourage individuals to make safe choices.

Key points

- ◆ Injuries and violence are a leading cause of mortality and morbidity worldwide.
- ◆ Injuries disproportionately affect young and vulnerable populations, and injury rates are disproportionately high among LMICs.
- ◆ Prevention of injuries is very feasible and works best with a multidisciplinary and integrated approach.
- ◆ A growing body of research and resources can help identify potentially effective approaches to prevent and reduce the consequences of injury.
- ◆ Building capacity for injury prevention should be a priority for all countries, but is an urgent need for LMICs.

Interpersonal violence: a recent public health mandate

Rachel Jewkes

Introduction to interpersonal violence

Violence is inherently a human rights violation that has a profound impact on the physical and mental health and social functioning of its victims and survivors. It is increasingly recognized to be a highly prevalent global problem, with wide-ranging health and social consequences, and a huge economic burden on countries. Interpersonal violence is, however, a social construct that is inherently preventable.

The *World Health Report on Violence and Health* described interpersonal violence as encompassing child maltreatment, youth violence, intimate partner violence, sexual violence, and elder abuse (Krug et al. 2002). This is a fairly robust categorization but it is important to recognize that interpersonal violence is not necessarily age or gender related. In settings where there is a pronounced culture of violence, adults of all ages may use violence to resolve conflict or assert dominance in a range of other settings including conflict between neighbours, in contexts of crime, in prisons, in the workplace, and between health professionals and patients.

Interpersonal violence is experienced and perpetrated by millions of people worldwide each year and the health and social impact is huge. In 2004, interpersonal violence was the 22nd leading cause of death, and 600,000 deaths worldwide were attributed to it, that is, 1 per cent of the global burden of mortality. In the age group of 15–44 years, however, interpersonal violence is among the leading cause of mortality. Future projections suggest that the contribution of interpersonal violence to global mortality over the next 15 years is expected to rise sharply, unless there is effective public health action to prevent it.

Commensurate with this scale of violence is a massive economic impact. A report published in 2004 estimated the cost of violence in the United States to be 3.3 per cent of the gross domestic product, and in England and Wales, the total costs from violence were estimated to amount to \$40.2 billion annually (Waters et al. 2004). A costing study of intimate partner violence estimated that in 2009 it was more than £15 billion in England and Wales alone (Walby 2010).

Magnitude of interpersonal violence

One of the most common forms of interpersonal violence is intimate partner violence. This encompasses physical, sexual, emotional and economic abuse, and a range of acts from threats of

violence, social isolation, intimidation, insults, through to rape, beatings and at the most extreme end of the spectrum, forms of torture. A recent systematic review concluded that globally 30 per cent of women aged 15 and over have ever experienced physical or sexual intimate partner violence (Devries et al. 2013). There is considerable variation in prevalence between global regions and settings. In the Eastern Mediterranean, Africa, and South East Asia the prevalence was 37 per cent, compared to 23–25 per cent in high-income countries, the Western Pacific, and European regions (World Health Organization (WHO) 2013). In some countries of the world, like South Africa, intimate partner violence is the most common cause of female homicide (Abrahams et al. 2013), and globally intimate partner violence is estimated to account for 36 per cent of female homicides (WHO 2013).

The global estimate for the proportion of women who have experienced non-partner sexual violence is 7.2 per cent (95 per cent confidence interval = 5.3 per cent to 9.1 per cent), with the prevalence ranging from 5 per cent in South East Asia to 12 per cent in Africa (Devries et al. 2013). Research with men on perpetration has shown that in some settings, including South Africa and Papua New Guinea, 20–40 per cent of men have ever raped a female non-partner (Abrahams et al. 2011; Jewkes et al. 2013).

Child abuse can be physical, sexual, or emotional and may also encompass physical and emotional neglect. Research has often used very different definitions and these often reflect cultural differences in normative child rearing practices. Comparability across settings can thus be hard, but one estimate from Gilbert was that in high-income countries each year 4–16 per cent of children are physically abused and one in ten is neglected or psychologically abused. Further during the whole of childhood, between 5 per cent and 10 per cent of girls and up to 5 per cent of boys are exposed to penetrative sexual abuse, and 15–40 per cent are exposed to any type of sexual abuse (Reza et al. 2007; Gilbert et al. 2009).

It was estimated in 2000 that 565 young people aged 10–29 die every day across the world from violence and that for each death 20–40 require hospitalization (Krug et al. 2002). The global youth homicide rate estimate was 9.2 per 100,000 people, but regional variations were substantial. This rate varied from 0.9 per 100,000 in high-income countries to 17.6 in Africa and 36.4 in Latin America (Krug et al. 2002). Youth violence is highly gendered, with the overwhelming majority of perpetrators and victims being male. Recent research for South Africa, for example, has shown that the

rate of homicide (21.7/100,000) for teenage boys (15–17 years) was nearly five times the teenage girls' rate (4.6/100,000) (Mathews et al. 2013).

Elder abuse is a much less researched form of interpersonal violence. Its subcategories generally include physical, psychological, sexual, financial, and discriminatory abuse and neglect. It is generally measured as exposure to people aged over 65 or over 60 (Cooper et al. 2008). The category is often measured in a way that fails to distinguish between other forms of violence experienced by older people (e.g. intimate partner violence) from violence that is a result of the constrained power of older people (i.e. because a person is elderly). This is an area that is growing in recognition, especially for elderly people with cognitive impairment. The main perpetrators are family members and care-givers. In some parts of sub-Saharan Africa a particularly horrific dimension of elderly abuse is seen in witchcraft-related violence and murders (Meel 2009). Understanding and preventing abuse of the elderly is an area that requires considerable further research.

Health consequences

The health impact of interpersonal violence extends well beyond the most immediate injuries and mortality. One area that has been the subject of considerable research is the intersections between HIV and gender-based violence. There is substantial evidence of the importance of gender inequity and intimate partner violence exposure in women's risk of acquiring HIV (Jewkes 2010; Jewkes et al. 2010b). Research from South Africa and Uganda shows that exposure to intimate partner violence raises HIV risk by about 50 per cent and that nearly one in four new HIV infections could be prevented if women were not subjected to intimate partner violence and relationship power inequalities (Jewkes et al. 2010b; Kouyoumdjian et al. 2013). Furthermore young women who have experienced sexual abuse in childhood are also at two-thirds greater risk of incident HIV infections (Jewkes et al. 2010b). Jewkes et al. argue that the evidence points to four key dimensions to the interface between gender inequity, violence, and HIV (Jewkes et al. 2010b).

First, women may become directly infected with HIV through rape. This is biologically inarguable and has been seen in clinical practice, yet population-based research suggests that the risks of HIV acquisition from rape are not great (Dunkle et al. 2004; Jewkes et al. 2010b). This is because the act is usually a single act of intercourse and the risks entailed in this are not very great. Further fears that rapists may be more likely than other men to have HIV, at least in South Africa have been shown to be unfounded (Jewkes et al. 2011b). None the less there is the potential for HIV acquisition during rape, in high prevalence sub-Saharan African countries many men who rape will be infected, and so it is vitally important that the violation of the rape is not compounded by preventable infection with HIV.

Secondly, women who experience more gender inequity and violence are less able to protect themselves from HIV, for example, they have sex more frequently and use condoms less often. The former may reflect a lesser ability to gain respect for their right not to have sex when they don't want it, but in some settings it may also reflect a practice of taking another partner for an emotionally more fulfilling relationship when trapped with a violent partner. Women who have more equitable relationships are much more able to use condoms consistently with their partner (Jama Shai

et al. 2010). This may be explained by women's ability to negotiate in such situations, but qualitative research points strongly to the acquiescence of women to male dominance in relationships and suggests that more commonly women who submit to unequal relationships are more likely to submit to an agenda of male control and so their own wants are not even considered (Jewkes and Morrell 2012).

Thirdly, childhood sexual abuse increases the risk of a range of risky sexual practices, including having multiple and concurrent partners, transactional sex, and substance abuse. All of these increase the risk of HIV acquisition as well as rendering women vulnerable to further partner violence or rape. Women who have experienced sexual abuse thus have a sustained elevated risk of HIV (Jewkes et al. 2010b). The mechanisms of increased risk are partly though the long-term mental health impact of child sexual abuse and often co-occurring emotional neglect, including an increased risk of post-traumatic stress disorder (PTSD) and substance abuse, as well as insecure adult attachment which is associated with increased rate of partner change and greater difficulties in emotional relationships. In this way abuse risks intersect with cycles of risk of violence and HIV.

Fourthly, ideals of marked gender hierarchy generally legitimize the use of violence in making and sustaining it, and often co-occur with ideals of masculinity that emphasize heterosexual performance, particularly toughness, strength, and having many partners (discussed later) (Jewkes and Morrell 2010). As a consequence, men who are violent towards women often engage in a range of sexually risky practices and some research has shown that they are more likely to be HIV infected (Decker et al. 2009; Jewkes et al. 2011b). If these research findings pertain more broadly, women partners of violent men are at higher risk of HIV acquisition per sexual act.

Interpersonal violence has a major impact on women's reproductive health. Childhood sexual abuse and child marriage increase the risk of early pregnancy and child bearing with higher maternal and infant mortality. Intimate partner violence also increases the risk of having had an induced abortion by more than twofold, young teenage pregnancy, and for those who have children the risk of a low birth rate baby is increased by 16 per cent (WHO 2013).

Child abuse has an important impact on mental health for boys and girls. Although there has been a strong emphasis in research on sexual and physical violence, the impact of emotional abuse and neglect is increasingly recognized. South African research shows that adolescent women who have experienced emotional neglect are at greater risk of depression, suicidality and alcohol abuse, and adolescent men were at greater risk of depression and drug abuse (Jewkes et al. 2010a). The same study found sexual abuse associated with alcohol abuse and depression in the men and alcohol abuse in the women. The impact of child abuse is discussed further later in this chapter. Mental health is also impacted by experience of intimate partner violence and non-partner rape. Women so exposed are at more than twice the risk of depression, and the latter group also have more than twice the risk of alcohol abuse (WHO 2013). Rape is also particularly likely to result in PTSD, and in fact is more likely to cause PTSD than any other violence exposure (Tolin and Foa 2006).

Interpersonal violence also has a range of social consequences including a greater risk of school dropout due to pregnancy, which

impacts on future employment and lifetime earnings. Violence results in more time off due to injury and its other health effects, and even women not working may experience social incapacity, impacting on childcare and homemaking.

Understanding its roots

On first reflection the category of interpersonal violence appears to consist of a disparate range of acts that share most acutely the use of physical force to cause hurt or injury. However, a deeper understanding of the roots of the different forms of violence awakens a realization that these are very profoundly interconnected. Firstly, in many cases the same people perpetrate different forms of interpersonal violence. For example, the aggressive young boy who bullies at school may later engage in violent fights with other youths, be sexually violent, violent to his partner, beat his children, and engage in group violence against an elderly woman accused of witchcraft. Whilst it's important to recognize that many people are violent in one context and not in others, violent behaviours are strongly patterned and a propensity to the use of violence in one situation does increase the likelihood of its use in others.

The second interconnection arises from the observation that many of the perpetrators of violence have themselves been victims. The most formative violence exposures in this regard are those of children to emotional or physical maltreatment, the trauma of witnessing intimate partner violence between parents, sexual abuse, and bullying. All of these are common exposures among those who perpetrate interpersonal violence and are risk factors for their doing so. Research with a nationally representative sample of US adolescents has shown that in its relationship with intimate partner sexual violence perpetration, experience of physical abuse in childhood is completely mediated by involvement in delinquent behaviour (Casey et al. 2009).

Except in the context of evenly matched gang fights, victims of interpersonal violence do not bring the violence on themselves, yet victimization is by no means random. For all forms of interpersonal violence there are factors that increase the likelihood of victimization and here again, an interconnectedness of forms of violence becomes visible. So women who have experienced sexual abuse as children are more likely to be re-victimized sexually as adults, and to experience intimate partner violence.

So how is the interconnectedness explained? There are three explanations of importance here. First, the different forms of violence have largely overlapping root causes and risk factors, which are discussed in more detail later. Second, the use of violence in conflict, to punish or otherwise assert dominance is a learned behaviour, and thus is part of culture. Violence's use has transferability between contexts, notwithstanding the differences between these. Social learning encompasses how violence is used and what forms it may take, who are appropriate victims, what are acceptable or required triggers for its use, what meanings will be attached to its use, and what patterns of reward or punishment can be expected to follow. In this way violence needs to be understood as inherently part of culture. For example, Wood et al. (2007) researching intimate partner violence in South Africa's Eastern Cape Province have shown that it is widely regarded as a normal part of gender relations and will be interpreted by the community, family, and victims as unexceptional providing the victim is not injured by the violence, indeed it is commonly interpreted as deserved, good for teaching the partner right from wrong, and is

socially rewarded to the extent that it may result in acquiescence. Whilst interpersonal violence is always culturally patterned, a further cultural dimension, which is often referred to as '*the*' culture of violence, relates to the threshold that triggers its use. Essentially there is marked cultural difference in the general level of triggers, with some societies, such as Papua New Guinea, having very low thresholds for the use of many forms of interpersonal violence. In other cultural settings, thresholds are very much higher, or the use of violence in general in interpersonal relations is viewed as inappropriate. Third, interpersonal violence is most commonly socially rewarded, at least at some level in the short term. There may also be very pronounced social rewards in contexts where 'men of violence' are revered, their physical power viewed with awe, and political power and economic rewards may flow from this. At a more micro-level, when violence is used to assert dominance and win submission this may be rewarded with the desired behaviour. Consequences for perpetrators may be quite different in the longer term, but in the short term it is often rewarded.

The fourth explanation lies in the nature and impact of victimization itself. Victims are often selected because they are vulnerable. Thus children who are disabled, mentally or physically less able, or very poor are more likely to be victimized. Victimization increases such vulnerability by causing disempowerment to be more acutely perceived, as well as often actually increasing disempowerment. Furthermore negative coping strategies after victimization, including problem drinking, may create vulnerability to further violence of other forms. In this way interpersonal violence creates cycles of vulnerability across different types of violence.

Risk factors for interpersonal violence

Risk factors for violence perpetration have been described as operating at a range of different ecological levels. This has been presented in an ecological model that highlights how some of these pertain and exert effects at an individual level, others at a family, peer or relationship level, others at a community level and still others at a societal level.

Individual level

Genotype

There is evidence that genes may be important in the development of aggression. Research points towards a general heritable tendency to antisocial behaviour, of which sexual coercion is one form. There may be important gene \times environment interactions, particularly with the expression of aggression in genetically susceptible individuals after exposure to a harsh environment, or else a person with antisocial tendencies might be more likely to be drawn to situations and settings where antisocial behaviour is more common or more possible (Johansson et al. 2008). The evidence is predominantly focused on non-sexual aggression. However both sexual aggression and general aggression are heritable in mice (Canastar and Maxson 2003) and one study of twins concluded that over a quarter of sexual coercion was explained by genetic factors, but the genetic element in psychopathy was higher (Johansson et al. 2008).

The monoamine oxidase A gene (MAOA) has been described as impacting on a heritable tendency for antisocial behaviour. This encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine (NE), serotonin (5-HT) and dopamine

(DA) and thus inactivates them (Shih et al. 1999). It is very rare for the gene encoding MAOA to have been deleted, although this is found associated with heritable aggression in humans and mice (Rowe 2001). More common are functional polymorphisms that result in lower activity of the MAOA enzyme (Caspi et al. 2002). A prospective study conducted in New Zealand has shown that child maltreatment has a much stronger association with subsequent antisocial behaviour in males with low MAOA enzyme activity, than those with higher activity (Caspi et al. 2002). In this study 11 per cent of violent convictions were attributable to the gene. Findings of research on exposure to physical punishment in early childhood, having the MAOA gene and likelihood of subsequent delinquency are inconsistent (Reif et al. 2007; Prichard et al. 2008; Edwards et al. 2010). The role of genetics in interpersonal violence, including sexual aggression, is clearly an important area for further work.

Other biological influences: androgens and neurological deficits and sexual offending

The role of androgens in interpersonal violence is questionable. A positive relationship between testosterone and self-reported aggressiveness has been reported for men and women (Christiansen and Knussmann 1987), but this has not been confirmed by all authors (Campbell et al. 1997). Several researchers have investigated links between blood testosterone levels and sexual or other aggression in prison populations, but found no evidence that testosterone levels influence the likelihood of sex offending, any more than general violent offending (Giotakis et al. 2003).

The role of brain damage in sexual offending has been the subject of research but the overall conclusion of a recent review of the literature is that the evidence is extremely weak (Fabian 2012). One of the few controlled studies with paedophiles found no differences on neuropsychological measures or positron emission tomography scans (Cohen et al. 2002). Whilst brain trauma may be important in some individuals, there is currently no evidence that brain damage makes an important contribution at a population level.

Early years' exposures

Irrespective of genotype, there is evidence that an individual's risk of perpetrating interpersonal violence can be shaped in the first days, months, and years of life. There is considerable evidence that perpetrators of interpersonal violence, including sexual violence, are more likely to have failed to form secure attachment bonds in childhood. This is linked to exposure to emotional, physical, and sexual abuse as well as to domestic violence, removal from the family, family disruption, and parental loss due to death or divorce may be risk factors for perpetration (Maniglio 2010).

Attachment

There is considerable evidence that the use of interpersonal violence is linked to a failure to form secure attachment bonds in childhood. One of the critical pathways through which the childhood home environment, particularly in early childhood, impacts upon psychological development is through attachment to primary caregivers, usually mothers (Bowlby 1969, 1973, 1980). If attachment bonds between the child and their primary caregiver are secure, children acquire the necessary skills to establish close relationships and grow to desire the intimacy of others. If these

bonds are insecure, children do not acquire the necessary skills to establish close relationships, and may grow to fear intimacy with other individuals, exhibit hostility or aggression within their relationships, or to seek intimacy in maladaptive ways (Bowlby 1969, 1973). The failure to form secure attachment bonds is due to poor socialization experiences, such as violent parenting, and disordered attachment has in particular been described as consequent of parenting that combines harsh punishment and expressions of affection (Fonagy and Target 2003; Marshall and Barbaree 1990). A failure to form secure attachment bonds in childhood results in a failure to learn interpersonal and other skills necessary to achieve intimacy as adults. Insecure attachments are marked by an expectation that what is needed will not be given, and as a result coercion, whether through physical violence, emotional manipulation or sexual violence, is often used to get it (Bowlby 1969, 1973, 1980). In the arena of relationships, insecurity may result in more dismissive and hostile attitudes towards others and a tendency to perceive others negatively and distrustfully. This has been shown in sex offenders, but is also likely to increase propensity to intimate partner violence, youth violence and interpersonal violence in the community (Marshall 1989; Stirpe et al. 2006; Whitaker et al. 2008). Individuals with disorganized attachment are much more aggressive, distrustful, and less empathetic when older and have a propensity to general interpersonal violence (Fonagy and Target 2003).

Dysfunctional parenting and disturbed family histories, with unstable caregiving often due to maternal post-natal depression, or parental intimate partner violence, have been shown to be associated with interpersonal violence and various categories of offending among children, including sexual offending (Lightfoot and Evans 2000; Seto and Lalumiere 2010).

Child abuse victimization

Physical and emotional abuse and neglect in childhood are exposures that result in a failure to form secure attachments. Emotional abuse and neglect has been subject to much less research than physical abuse, but a multicountry study on men's violence in Asia and the Pacific has shown that men who rape non-partners and those who have been violent to intimate partners are more likely to have been exposed to all of these in childhood, and these findings support the research from South Africa (Fulu et al. 2013; Jewkes et al. 2011a). In contrast to this, a large national study of adolescents from the United States found that those who had been sexually violent to a partner were significantly more likely to have experienced physical abuse themselves, but not emotional neglect (Casey et al. 2009) and another did not find sexually violent youth to be more likely to have experienced physical violence (Borowsky et al. 1997).

The evidence of childhood sexual abuse as a risk factor for subsequent perpetration is very extensive and probably has been the most comprehensively investigated of all risk factors for perpetration. In a meta-analysis, a history of child sexual abuse was five times more common among adolescent sexual offenders than among adolescent non-sexual offenders (Seto and Lalumiere 2010). Further, sexual offenders against children are much more likely to have sexual abuse victimization histories than non-offenders or non-sexual offenders (Whitaker et al. 2008). Several large national studies of US adolescents and men in college have found that those who had sexually assaulted a partner were significantly more

likely to have experienced sexual abuse themselves (Borowsky et al. 1997; Casey et al. 2009; Malamuth et al. 1991, 1995).

Witnessing intimate partner violence in the home is both extremely traumatic for children and may be part of social learning about intimate relations. Both of these may explain the consistent finding that men who have been so exposed in childhood are more likely to be physically or sexually violent towards their intimate partners (and girls so exposed to experience violence themselves) (Malamuth et al. 1991, 1995; Borowsky et al. 1997; Fulu et al. 2013). South African research has also shown that men who have been exposed in childhood are more likely to get involved in fights at work and in the community, and have been arrested for having an illegal firearm (Abrahams and Jewkes 2005).

Personality

These early years of exposure have a profound impact on personality when older. Psychopathy has been the most extensively discussed in relation to perpetration of interpersonal violence. Psychopathy is a constellation of personality traits and socially deviant behaviours, spanning affective, interpersonal, and behavioural traits. Hare has proposed that the characteristics of psychopathy include egocentricity, lack of remorse and empathy, pathological lying, manipulativeness, and the persistent violation of social norms (Hare 1996). These traits enable psychopaths to treat others as objects and feel no guilt or remorse. They are thus much more likely to perpetrate interpersonal violence, particularly severe physical violence, emotional violence, and rape.

In the US general population the prevalence of psychopathy is usually estimated at 1 per cent, but the prevalence of psychopathic traits without a full clinical diagnosis is higher (Lilienfeld 2005). Individuals with heightened levels of some of the characteristics of psychopathy have been described as subclinical and non-clinical psychopaths (LeBreton et al. 2006). The prevalence of psychopathy as a diagnosis is dependent on assessment measure scores. Research on Canadian incarcerated sex offenders shows that a relatively small difference in cut point (25 versus 30) on the PCL-R (Hare Psychopathy Checklist—Revised) (Hare 2003) resulted in twice as many offenders being diagnosed as psychopathic (29 per cent vs. 13 per cent) (Olver and Wong 2006). This suggests that the presence of psychopathic traits may be important in understanding interpersonal violence at subclinical levels and indeed this has been suggested by research in South Africa where two traits were measured, Machiavellian egocentricity and blame externalization, and were significantly higher among men who had raped in both the past year and their lifetime (Jewkes et al. 2011a). There are similar findings from US college students, among whom sub-clinical scores on psychopathic traits have been associated with rape perpetration (Abbey et al. 2011; DeGue and DiLillo 2004; Ouimette 1997). Psychopaths have been described as having an inability to connect sexual behaviour with emotional feelings, such as warmth and tenderness, and a hedonistically orientated lack of impulse control and are thus more likely to be sexually as well as physically violent (Cleckley 1988).

Personality disorders of offenders

Research on personality disorders in populations of offenders shows that sex offenders against children and adults show significantly more Cluster A, Cluster B and antisocial personality disorders than non-offenders (Whitaker et al. 2008). Psychopathy

is common among more violent child sex offenders (Rosenberg et al. 2005). Schizoid personality features include social detachment and restricted emotionality, and avoidant features include social inhibition and inadequacy. Both of these interfere with the development of normal peer relationships, including intimate relationships with women, and are more prevalent among sex offenders, particularly against children (Fazel et al. 2002; Whitaker et al. 2008). Men who sexually molest children are socially and emotionally immature, have poor social skills, low levels of self-esteem, poor impulse control, and more signs of psychotic thinking (Finkelhor and Araji 1986). Relating to children provides a sense of power and control and opportunity for dominance not available to them in adult relationships (Finkelhor and Araji 1986).

Substance abuse

Alcohol abuse is strongly associated with use of interpersonal violence. There are physiological effects, but also complex cultural beliefs about and meanings given to the relationship between alcohol and violent, including sexually violent, behaviour. Alcohol has a physiological effect of reducing inhibitions, reasoning, and, in men who were more irritable, prone to anger and have low levels of anger control, can result in ready use of violence (Finkelhor and Araji 1986). Research on intimate partner violence and rape in particular commonly finds that men who are violent are more likely to have heavy alcohol use (Koss and Dinero 1988; Jewkes et al. 2006, 2011a; Tsai et al. 2011; Fulu et al. 2013). Many cultures (or subcultures) link alcohol consumption to disinhibition, sexual desire, and performance, and perceive it to give courage to make advances that men may be reticent to make when sober, and as mitigating antisocial or aggressive behaviour (Lightfoot and Evans 2000; Seto and Lalumiere 2010). Alcohol abuse also has an economic impact on families, leading to greater financial strain, and may be a trigger for conflict over finances.

A further question is whether violence associated with alcohol more often results in serious injury or mortality. There is some evidence that shows that when a perpetrator is drunk and the victim sober there was a greater likelihood of rape completion and victim injury than when they had both been drinking (Brecklin and Ullman 2002). In the case of youth homicide, alcohol is estimated to be responsible for 26 per cent and 16 per cent of years of life lost by men and women respectively, with the proportion lower in high-income countries and as high as 40 per cent in low-income countries (WHO 2004).

Drug use

Drug use is also intimately connected with youth violence and homicide, most directly because the trade in drugs in many settings is associated with violence and turf wars between dealing gangs (Blumstein et al. 2000). Research on rape has shown that men who have raped are more likely to use drugs, indeed a prospective study from South Africa concluded that 24 per cent of all rapes would have been prevented if drug use had not occurred (Jewkes et al. 2012). The great majority of the drug use reported was marijuana use, but the authors argued that drug use was most likely an indicator of engagement in a subcultural peer context where both drug use and rape was seen as 'normal' (Jewkes et al. 2012). This conclusion is supported by findings of a multicountry study that drug use was associated with having ever engaged in

multiple perpetrator rape (sometimes referred to as gang rape), but not single perpetrator rape (Jewkes et al. 2013).

Depression

There is evidence that men who use violence against intimate partners are more likely to be depressed (Nduna et al. 2010; Fulu et al. 2013). It is not clear whether depression causes men to become violent, or is an emotional response to having used violence and the negative impact that this has on a relationship. It is possible that, as with alcohol abuse, depression and feelings of hopelessness may exaggerate irritability in men who are inherently more irritable and prone to anger, and as a result they may more readily use violence.

Propensity to use violence

The use of interpersonal violence in one context is closely related to its use in others. This has particularly been highlighted in the relationship between perpetration of violence against children and sexual violence against non-partners by men who have been physically or sexually violent to an intimate partner. Rape of non-partners has been found to be more common among men who are physically violent towards partners (Malamuth et al. 1991, 1995; Jewkes et al. 2006, 2011a, 2013). It seems likely that a system of patriarchy and gender hierarchy that legitimates the use of physical violence by men to assert dominance in a relationship and 'correct' behaviour of wives and girlfriends would also find expression in sexual violence, as well as other forms of violence, such as verbal violence. There is also some evidence that verbal violence against women is more common among sexually coercive men in US colleges and among South African working men (Malamuth et al. 1991, 1995; Abrahams et al. 2004).

Relationship, peer, or micro-social level

Conflict

The dynamics of particular relationships are also important influences of the propensity for use of violence. Intimate partner violence is more common in relationships that are more conflictual, and experimental evidence suggests that interventions that build communications skills and reduce relationship conflict are impactful in reducing intimate partner violence (Jewkes et al. 2008). Poor communication skills of either partner may result in conflicts escalating readily to violence. Conflict escalating to violence is also more common in relationships where one partner is more irritable and prone to outbursts of anger. Perceived challenges to men's 'right' to what they perceive as traditional gender privileges and their non-fulfilment of expected provider roles are often causes of conflict.

Social learning around violence acceptability

In teenage peer relationships, it has been observed that friends are similar in their characteristics in a wide range of domains and aggression is no exception (McPherson et al. 2001). There has been considerable debate about whether aggressive young people choose each other as friends or whether as friends they become more similar in regard to aggression (Snyder et al. 1997; Steglich et al. 2010). There has been limited longitudinal research, but one study from Chile suggests that children do not select friends based on their levels of aggression, rather that similarity among friends is a product of the friendship, although it is also possible that aggressive male youth may be forced together if non-aggressive peers

reject them (Steglich et al. 2010). This partly explains the strong connection between gang membership and violence perpetration that has been described in many settings (Bourgois 1996; Jewkes et al. 2006, 2011a). The importance of perceived social acceptability of violence was also highlighted by a study that found the parents of violence perpetrators, when compared with parents of non-perpetrators, were much more likely to have encouraged gang membership (Morris et al. 2002).

Social learning about sexual violence as normative, is demonstrated in research with incarcerated American adolescents that has shown that sexual assault perpetrators were nearly four times as likely as non-perpetrators to know a perpetrator of sexual assault (Morris et al. 2002). Among a community-based sample of men, perceived peer approval of coercing sex was much higher among men who rape (Abbey et al. 2007). A further aspect of social learning is reflected in the perpetration of sexual abuse by those who have themselves been sexually abused in childhood. Research from New Zealand provides an additional perspective on this as sexually abusive adolescents and children were found to have been more likely to have had contact with adults who were known paedophiles or suspected to have engaged in sexual abuse of other children, even when they did not have confirmed sexual abuse victimization themselves (Lightfoot and Evans 2000). These children may have experienced abnormal sexualization through exposure to inappropriate sexual experiences (e.g. pornography exposure or verbal experiences) (Lightfoot and Evans 2000).

There is also a social learning element in the use of violence in child rearing practices, particularly physical punishment. Physical violence is generally used to punish or gain control over a child and is used more readily by parents raising children in contexts where beating is more common and where there is less role modelling of non-violent parenting and discipline practices.

Delinquent behaviour

The use of interpersonal violence, including rape, among adolescents is strongly associated with other antisocial behaviour (Ageton 1983; Calhoun et al. 1997; Malamuth et al. 1991; Knight and Sims-Knight 2003). Delinquency is an area where multiple risk factors and violent behaviour intersect. There may be genetic roots in some young men, as research has shown that men with genetically determined low MAOA enzyme activity and exposure to harsh punishment in early childhood are more likely to become delinquent (Edwards et al. 2010). Further it is strongly related to personality traits of psychopathy, which themselves may be genetically determined (Abbey et al. 2011). Delinquency is also socially modelled and much more common among youth who have themselves experienced physical aggression in childhood, and are more susceptible to peer pressure (Malamuth et al. 1995; Casey et al. 2009).

Multicountry research on both intimate partner violence perpetration and rape perpetration has shown that these are associated with having currently or previously been in a gang (Borowsky et al. 1997; Jewkes et al. 2011a; Fulu et al. 2013). They are also associated with having been involved in other interpersonal crime or theft, having a weapon, and having had an illegal gun (Jewkes et al. 2011a; Fulu et al. 2013). School bullying is one manifestation of delinquent behaviour, and often a precursor of antisocial behaviour in adulthood (Bender and Lösel 2011). South African research has shown perpetration of school sexual bullying to be

strongly associated with subsequent rape perpetration (Jewkes et al. 2011a).

One of the important avenues in the prevention of delinquency is health and education sector interventions for children with conduct disorders. Children with conduct disorders may go on to develop personality disorders as adults, particularly antisocial personality disorders. Conduct disorders are treatable in children, but they require parents to be trained in managing problem behaviour, or out-of-home placements with staff or foster parents appropriately trained. Treatment is most effective when provided to younger children (pre-adolescent); this has been part of the theoretical basis for the Incredible Years programme of Webster-Stratton and colleagues.

Masculinities and delinquent peers

Gang or otherwise delinquent peer contexts are also ones in which the masculinities of involved boys are shaped. Negative early childhood influences that generate feelings of insecurity greatly increase the likelihood that as boys grow into men they will adopt masculinities that emphasize strength, toughness, and demonstrate control over others. Such masculinities are familiar within a gang, or otherwise pugilistic peer context, where there is a readiness to show toughness among gang members, between them and potential rivals, dominance over women and to display power over others (e.g. in the context of crime).

Within any social setting there are multiple ways of, and aspirations for, being a man or boy. Some subcultural masculinities are particularly violent, and emphasize dominance over women, with a heightened sense of male sexual entitlement, which readily translates into rape (Bourgois 1996). This is particularly commonly found associated with gangs and among men positioned on the antisocial fringes.

Community level

Many of the structural drivers of interpersonal violence operate at a community level. These include poverty, patriarchy, and structural influences on these such as race or ethnicity. In a profound way these impact on the culture of the local context.

Poverty

Poverty, low educational attainment, and social disadvantage are structural drivers of interpersonal violence. Gangs, which are archetypically associated with many forms of violence, are very largely confined to life in low-income areas. In conditions of poverty, gangs provide young men access to experiences of power when other routes of attainment of power and status are unattainable, such as through working or fulfilling provider roles (Bourgois 1996; Wood and Jewkes 2001; Wood et al. 2007). Poverty increases the risk of intimate partner violence and child maltreatment both because it increases economic strains on families and relationships, and also because it generates feelings of inadequacy and powerlessness that may be expressed through the use of violence. Poverty further traps women within violent relationships and can reduce their options for taking action to protect themselves, or to get the violence to stop. Economic empowerment interventions for women have been shown to be a very fruitful avenue for enabling women to protect themselves from intimate partner violence (Pronyk et al. 2006).

The relationship between rape and poverty is complex. Multiple perpetrator (gang) rape is most clearly linked to poverty because

this is important in the context of gangs (Jewkes et al. 2013). The role of social disadvantage in single perpetrator rape is less clear because perceptions of sexual entitlement are a very powerful part of the context of rape and these may stem from social advantage rather than disadvantage. South African research has shown that among the less well off, it is the slightly less poor or less disadvantaged who are more likely to have raped (Jewkes et al. 2006, 2011a). Authors have argued that a sense of entitlement stemming from relative advantage, within a context of general disadvantage, is played out in a perverse way in a context in which few or none would be able to attain objectively high levels of material 'success' (Jewkes et al. 2011a).

Social norms: the cultural scaffolding for interpersonal violence

For all forms of interpersonal violence, social learning around the acceptability of the use of violence, and for gender-based violence, the acceptability of directing it to women, within subcultural contexts is important in perpetration. The importance of social norms on the use of violence in partner violence perpetration was first made visible by anthropological work looking at factors associated with violence across a wide range of cultural settings (Levinson 1989). More recently research on intimate partner violence has increasingly explored the importance of community level norms on the use of violence, for example indicated by community murder rates, as a risk factor for intimate partner violence and found it to be highly associated (Koenig et al. 2006).

Social norms on gender relations and violence are also very important. The phrase 'cultural scaffolding' was coined by Gavey to describe the protective social context that enables the reproduction of sexual violence through allowing men to reconfigure sexually coercive behaviour, especially with dates, girlfriends, or wives as 'not rape' (Gavey 2005). The scaffolding includes an array of rape myths that place the blame for rape at the feet of women and enable a cognitive justification for coercive behaviour, ideas of sexual entitlement within marriage (conjugal rights), and the positioning of women as worthy objects of male sexual conquest. This scaffolding is argued to stem from a framework of patriarchy whereby men are positioned as hierarchically superior to women and accorded greater social value. This ideological scaffolding provides the cultural space for men to perpetrate rape without embracing an identity as 'a rapist' or 'a perpetrator'. Similarly youth violence and bullying are often seen as being normal for the age group and is seen as 'not violence' but more the rough and tumble of growing up (Wood and Jewkes 2001).

In some settings the use of interpersonal violence is integrally related to culturally constructed notions of legitimate entertainment. This is very clearly seen in research on rape where men have been asked about their motivations. For example, in a six-country study on men's use of violence in Asia and the Pacific 59 per cent of men who had raped a non-partner indicated that one of the reasons they did it was for entertainment (Jewkes et al. 2013). In South Africa, seeking 'fun' motivated nearly half of South African men who had raped (Jewkes et al. 2011a). Quite similar findings pertain in youth violence, where research in the United Kingdom has shown that fights in bars are very often started for fun (Graham and Wells 2003).

The cultural scaffolding around child abuse is such that physical violence used by caregivers against children is often described as being 'necessary' in order to teach children how to behave and

instil discipline, and is thus seen as 'not violence'. In many cultures the use of violence in child-rearing is so ubiquitous that many parents and teachers cannot imagine that there is any other way to properly raise children. Further settings such as in sub-Saharan Africa, societies are characterized by a very pronounced age hierarchy (as well as gender hierarchy) and children are raised to be obedient to adults in all ways, including to relative strangers. This can lead to children being placed in positions of vulnerability, especially to sexual abuse (Jewkes et al. 2005).

Masculinities

The most pervasive ways in which culture influences interpersonal violence is in the arena of gender. Gender attitudes held at an individual level are usually rooted in cultural models of gender relations, but within these there is considerable individual variation. Sexually aggressive men from diverse settings have greater hostility towards women, stronger sexual dominance desires, and more traditional attitudes towards gender roles and sexual relationships (Koss and Dinero 1988; Malamuth et al. 1991, 1995; Abbey et al. 2011; Jewkes et al. 2011a). Intimate partner violence is much more common among men who hold more gender inequitable views as well as those who engage in more controlling behaviours (Fulu et al. 2013). However, individually held attitudes and social norms theory do not on their own explain the social structure of gender. R.W. Connell (1987), a highly influential gender theorist, describes the existence of multiple, mutable masculine positions and identities, that are produced against a backdrop of history, cultural, and material circumstances, arranged hierarchically with respect to each other (some are viewed as legitimate whilst others are censored), and superior to women. Recognizing the global dominance of patriarchy, Connell argues that all masculine positions are constructed within a gender value system that values men over women and within which men are more powerful. Connell emphasizes that gender identities are socially constructed and integrally linked to hierarchies of power. Her analysis is critical to understanding both gender relations (i.e. between men and women) as well as the interrelationships among men. Connell argues for the existence in a particular setting of a hegemonic masculinity, which is a cultural ideal of manhood that gains its legitimacy from acceptance that is shared between those who embody and benefit from the ideal and those subordinated through it (after Gramsci (1971)). Hegemony connotes the existence of agreed values and practices, not necessarily associated with repression and violence. However, in many contexts, being dominant and in control of women are important aspects of hegemonic masculinity, and violent behaviours are justified in pursuit and demonstration of this (e.g. Wood and Jewkes 2001).

The different masculine positions that are adopted by men in a given setting vary, but there are global commonalities that have been observed. The first is that in any given setting there are normally masculinities that are notably violent and combine practices of violence between men with violent domination over others, particularly women. Men who adopt these masculine positions often are involved in illegal and antisocial behaviour. Further their dominance over women encompasses both the use of violence against women and demonstrations of power through (hetero)sexual success with or dominance over women, for example, in paying for sex, having many sexual partners, and so forth. These masculinities are sometimes referred to as hyper-

emphasized masculinities and are very closely associated with violence between men as well as sexual and physical violence against women.

The hegemonic masculinity within a given setting is much more moderate than this. It may not be numerically the most common position, but has the greatest cultural power, in that it is a masculinity that generally embodies a recognized cultural ideal of how men 'should' be, even if some men are unable to occupy the position due to economic circumstances. Hegemonic masculinities vary considerably globally, particularly in their relationship with men's violence. In some settings, such as South Africa, showing toughness and strength is absolutely integral to a hegemonic position. Men may be expected to be head of a household, a provider, and for women to be obedient. The cultural legitimacy accorded to a hegemonic masculine position results in men being able to exercise power over women without the use of violence, rather through women's acquiescence to men's dominance, but violence may be used. In some countries, such as Sweden, hegemonic masculinities are much more gender equitable and not expected to entail violence (Hearn et al. 2012). The relationship between hegemonic masculinity and the use of violence is extremely important in understanding the prevalence of interpersonal violence within a given cultural setting.

There are of course other masculinities and some are much more gender equitable and less violent, even in contexts of very patriarchal hegemonic masculinities. Some are constructed as resistance masculinities and may strive to be different, as is the case with gay masculine identities. Hegemonic masculinities often emphasize heterosexuality and are constructed very consciously in opposition to the feminine or homosexual, and indeed men may be identified as victims of male violence because they are perceived as being 'unmanly'.

The importance of masculinities in interpersonal violence should not mask the role of women. Women are responsible for perpetration of much violence against children, but for other forms of interpersonal violence the majority of perpetrators are men. Women do use violence against intimate partners, but much of it is retaliatory violence and where they initiate it their violence differs in meaning with the violence of men because it is not perpetrated within an overall context of gender power inequity. They also may engage in youth violence with other women. In a given setting women also adopt multiple feminine positions, some of which are highly acquiescent to dominant positions of men. These positions may render women vulnerable to violence but they may also provide some protection. Femininities which are constructed as resistance femininities may be viewed by men as threats and make women deliberate targets of violence, for example, in attacks on lesbians. There is an increasing literature from high-income countries and some settings with rapid social change, such as South Africa, on 'modern' femininities. These are characterized by women adopting many of the practices of men, without necessarily challenging the dominance of men in the gender order. They may be associated with particularly risky behaviour such as fighting among women, binge drinking, and having many sexual partners (Jewkes and Morrell 2012).

The importance of understanding gender identities in relation to interpersonal violence is that they provide a unifying framework for understanding both male dominance over women and the use of violence between men and between women. Other

connected practices such as alcohol bingeing very often stem from links between alcohol excess and control and toughness, or alcohol and resistance (e.g. in conservative settings), which is highly gendered. It also connects interpersonal violence with some of its associated sexual practices and associated health risks. First, by linking gun or weapon ownership, or carrying, with manhood. Secondly, sexual assault and rape perpetrators from a range of countries, including the United States, South Africa, Botswana, and Swaziland, have more dating and consensual partners and more casual sex than other men, although they may not have more frequent sex as they have less emotionally engaged relationships with partners (Koss and Dinero 1988; Malamuth et al. 1991, 1995; Abbey et al. 2006; Jewkes et al. 2006, 2011a, 2011b; Kalichman et al. 2007; DeGue et al. 2010; Tsai et al. 2011). Changing the values upon which gender identities are constructed is an important avenue for intervention in interpersonal violence reduction.

Stigma

Gender values of a society are also expressed in perceptions of blame in cases of gender-based violence and in social responses to victims. Rape stigma is particularly powerful as it may be expressed in perceptions that women and girls who have been raped are sullied, and to blame for what happened, and this can lead to their ostracism. In some settings the rape is seen as a mark against the family's honour and not just a woman's own, and they may even be killed. Children born of rape may be rejected by families and communities too. Rape stigma is a very substantial barrier to access to services and legal redress after rape, and thus creates impunity for those who perpetrate.

Societal level

At a societal level it is important to understand that the dominant social values, especially gender values, are expressed in laws, policies, and through social institutions such as the police and courts. Thus in very patriarchal societies, except in settings with deliberate initiatives to build human rights (such as South Africa), laws very often restrict women's autonomy and may increase their vulnerability to violence and reduce their ability to bargain with, or leave, violent partners. Examples of such laws are those that make divorce hard to access, allow parents to marry very young girls, fail to criminalize rape in marriage, restrict married women's access to property and inheritance, or render women as legal minors.

Dominant values are also reflected in legal systems even where laws are more progressive. The police may refuse to open cases if they believe an act not to be a crime, this has particularly been reported in cases of rape and domestic violence. Courts may have a low threshold for declining to prosecute and where women are viewed with suspicion their evidence in court may be insufficient for a conviction (Jewkes and Abrahams 2002). If women cannot get legal redress for acts of intimate partner violence or rape or child abuse, perpetrators are sent a powerful message that they may anticipate impunity and that their acts are not viewed as serious.

At a societal level, laws may influence access to risk and protective factors including alcohol. In some countries alcohol is very cheap, easily accessible at all hours, and poorly regulated. These factors result in considerably higher alcohol consumption patterns, especially by young people, and so to a stronger link between interpersonal violence and heavy drinking. Similarly firearms are

very effectively controlled by laws in some settings. South Africa is an example of a country where tighter gun control translated into a substantial reduction in gun-related homicides, these accounted for 17 per cent of female homicides in 2009, a reduction of nearly 50 per cent from one decade earlier (Abrahams et al. 2013). In comparison in the United States, with its very liberal gun laws, 67.5 per cent of homicide is perpetrated with a firearm.

Summarizing the prevention challenge

There have been a number of systematic reviews that have sought to summarize the evidence for what works in interpersonal violence prevention and the field in many areas is growing rapidly. A key review of interventions evaluated with randomized controlled trials for preventing sexual and intimate partner violence was published by the WHO (WHO and London School of Hygiene and Tropical Medicine 2010). The challenge in interpersonal violence prevention can be summarized as one that requires three avenues of intervention. The first are interventions to reduce the risk of the perpetration of interpersonal violence. Here the task, starting from the start of life, is to build a supportive home environment, with interventions to strengthen parenting, reduce exposure of children to all forms of violence, and provide treatment for depression and substance abuse, as well as increasing understanding of good parenting practices. There are a range of interventions that have been shown to be effective in high-income, as well as low- and middle-income settings in this regard. There have also been a series of key systematic reviews showing that interventions are effective in reducing child maltreatment and strengthening positive parenting (McCloskey 2011; Knerr et al. 2013).

Prevention requires changes to constructions of masculinity that emphasize dominance over women and legitimize the use of violence between men. Interventions, such as Stepping Stones and Program H, have been shown to be effective in changing masculinities, as well as some school-based programmes (Welbourn, 1995; Wolfe et al. 2009; Ricardo et al. 2012). The key challenge is to scale up interventions that are known to be effective and overcome the vested interests of patriarchy that resist prioritization of this endeavour. Addressing and acknowledging the context of poverty, low school achievement, and underemployment of men and teenage boys which provides the backdrop for interpersonal violence is also important, but research shows that change can occur within this context. Interventions that empower and build relationship skills, particular communication skills, and conflict skills are also very important in reducing all forms of interpersonal violence.

Interventions to address social norms on the use of violence are important and creating violence-free environments, especially schools with zero tolerance for bullying and violence, is very important. Abolishing the use of corporal punishment in schools, as well as homes, is also an important part of the agenda. In settings where it is entrenched, evidence suggests that outlawing it has a contribution but teaching positive discipline to teachers is critical to ensure its eradication.

The second broad intervention focus aims to socially and economically empower women and girls, to protect themselves from victimization, and to support themselves if they do want to leave a violent relationship; and to change societal norms and expectations about gender roles and relationships, including the acceptability of different forms of gender-based violence, which provide a self-perpetuating learning environment in which boys may grow

up to expect to be able to use violence against girls and to normalize its use against them. There has been a recent burgeoning of research into the role of economic empowerment of women in intimate partner violence prevention, following the success of the Image study (Pronyk et al. 2006). Understanding the role of economic empowerment within the broader basket of interventions and the contexts in which it is most effective is critical.

The third intervention is to strengthen formal and informal legal, health, and social support structures and prevention. These interventions aim to increase accountability for violence and prevent further violence from occurring, as well as trying to break the intergenerational cycles of violence that are commonly seen. Interventions include strengthening laws, child protection systems, improving the functioning of police and courts in cases of interpersonal violence, and adopting and enforcing a range of other legislation and policies to reduce risk including those focused on gun control and the prevention of problem drinking.

This prevention agenda is an ambitious programme, but we do know that interpersonal violence can be prevented. The best confirmatory evidence of this comes from the United States, where the prevalence of all forms of interpersonal violence has very substantially declined over the last 20 years. For example child maltreatment and victimization is believed to have declined by 40–70 per cent (Finkelhor and Jones 2006), intimate partner violence has declined by 49 per cent, and figures from the Federal Bureau of Investigation show that the homicide rate declined from 9.8 to 4.7 per 100,000 from 1990 to 2010, making the current homicide rate comparable to that of 1960. Unfortunately it is much less clear which interventions worked. Criminologists and public health researchers have extensively debated the causes of the decline, because of the importance of understanding this for its replication in other settings, but unfortunately they only agree that they do not know how to attribute it. However, it was a period when there was much more public health intervention to raise awareness of, and the prevention of, child maltreatment. There was a 24 per cent reduction in families living in poverty and there were increasing policing interventions and crime reduction activities, as well as a range of other social changes including changes to build gender equity (Finkelhor and Jones 2006). The clustering of reduction in all forms of interpersonal violence (except child neglect, but this may be an artefact of case identification) strongly supports an argument that they are all closely interconnected and the need for a multipronged approach to prevention.

Conclusions

Interpersonal violence is a problem of huge global magnitude, responsible for a very substantial global burden of disease and with considerable economic impact. It is largely preventable and this chapter has sought to argue that although forms of interpersonal violence differ, prevention can substantially be unified as there are a common set of risk factors. Further when interpersonal violence does decline, as in the United States, a decline across all forms is seen to occur. Social norms around gender and the use of violence are extremely important in all forms of interpersonal violence and need to be a key focus for intervention. The prevention agenda in interpersonal violence, especially gender-based violence and child maltreatment, has historically been dominated by secondary prevention, with responses from child protection

and the criminal justice system and the provision of services to victims. This is very important, but it is only a small part of the prevention agenda. First prize for the future will go to developing robust multisectoral primary prevention interventions that have an impact on multiple risk factors and change the social context within which interpersonal violence occurs.

Collective violence: war

Barry S. Levy and Victor W. Sidel

Collective violence as threat to public health

In 1966, the World Health Assembly declared violence ‘a major and growing public health problem across the world’ (World Health Assembly 1996). The *World Report on Violence and Health*, published by the World Health Organization (WHO) in 2002, was the first comprehensive report by the WHO on violence as a public health problem (Krug et al. 2002). The WHO report presented a typology of violence that defines three broad categories based on the characteristics of those committing the violent acts: self-directed violence, interpersonal violence, and collective violence. Other chapters in the textbook cover the first two categories of violence (see Chapters 8.7 and 9.5), and this chapter will deal primarily with war, an important component of collective violence.

Collective violence has been characterized as ‘the instrumental use of violence by people who identify themselves as members of a group—whether this group is transitory or has a more permanent identity—against another group or set of individuals in order to achieve political, economic, ideological, or social objectives’ (Krug et al. 2002, p. 215). Collective violence includes armed conflict (such as war), state-sponsored violence (such as genocide, repression, disappearances, and torture), and organized violent crime (such as gang warfare and banditry).

The *World Report* gives examples of collective violence: ‘Violent conflicts between nations and groups, state and group terrorism, rape as a weapon of war, the movement of large numbers of people displaced from their homes, and gang warfare’ (Krug et al. 2002, p. 215). As the *World Report* notes, ‘all of these occur on a daily basis in many parts of the world’ and ‘the effects of these different types of events on health in terms of deaths, physical illness, disabilities, and mental anguish are vast’ (Krug et al. 2002, p. 215). Also included in this chapter is limited information on what has been termed *terrorism* and the *war on terror*, as Chapter 8.18 covers *bioterrorism*. This chapter will not cover the topic of *gang warfare*, which is covered in Chapter 9.5.

The health impacts of collective violence

Direct consequences of war and military operations

Armed conflicts in the twenty-first century largely consist of the civil wars (conflicts within countries, to which other countries sometimes contribute military troops). In the 2001–2010 period, there were 69 armed conflicts globally; in 2010, 30 of these armed conflicts were still active. Of these armed conflicts, those that

result in 1000 battle-related deaths within a year are classified as wars. In 2001, there were ten wars; in 2010, there were four wars, including the Iraq War (Stockholm International Peace Research Institute 2012; Levy and Sidel 2013a). During the 2001–2010 period, there were 221 non-state conflicts (the use of armed force between two organized groups, neither of which is the government of a state, that results in at least 25 battle-related deaths in a year); the number of non-state conflicts per year decreased during this period, with 26 non-state conflicts active during 2010 (Stockholm International Peace Research Institute 2012).

Some of the impacts of war on public health are obvious, whereas others are not. The direct impact of war on mortality and morbidity is apparent. Many people, including an increasing percentage of civilians, are killed or injured during war. An estimated 191 million people died directly or indirectly as a result of conflict during the twentieth century, more than half of whom were civilians (Rummel 1994). The exact figures are unknowable because of the generally poor recordkeeping in many countries and its disruption in time of conflict.

War has direct, immediate, and deadly effects on human life and health. The ‘body counts’ and the data on those with war-caused injuries and disabilities, both physical and psychological, although woefully incomplete, document the many people tragically killed and wounded as a direct result of military activities. Through the early twentieth century up to the start of the Second World War, the vast preponderance of the direct casualties of war were uniformed combatants, usually members of national armed forces. Although non-combatants suffered social, economic, and environmental consequences of war and may have been the victims of what is now termed *collateral damage* of military operations, ‘civilians’ were generally not directly targeted and were largely spared direct death and disability resulting from war (Levy and Sidel 2008).

However, since 1937, when Nazi forces bombed the city of Guernica, a non-military target in the Basque region of Spain, military operations have increasingly killed and maimed civilians through purposeful targeting of non-military targets. The use of ‘carpet bombing’ and the collateral damage of heavy attacks on military targets have caused many civilian casualties. The percentage of civilian deaths as a proportion of all deaths directly caused by war has therefore increased dramatically. Many of these civilian deaths may have been indirectly rather than directly caused by war.

Since September 11, 2001, there has been increasing concern in the United States and other countries about violence conducted by individuals and groups to create fear and advance a

political agenda—a form of violence commonly called *terrorism*. We believe that there needs to be a balanced approach to strengthening systems and protecting people in response to the threat of terrorism, an approach that strengthens a broad range of public health capacities and preserves civil liberties (Levy and Sidel 2012). Terrorism is often defined in a partisan fashion: those called *terrorists* by one side in a conflict may be viewed as ‘patriots’, ‘freedom fighters’, or ‘servants of God’ by the other. We have defined terrorism as, ‘politically motivated violence or the threat of violence, especially against civilians, with the intent to instil fear’. This definition includes violent acts conducted by nation-states against civilians with the intent to instil fear as well as acts committed by individuals and subnational groups. The term *terrorism* has considerable overlap with the term *war* and many actions conducted during war fit our definition of terrorism. The ‘war on terror’ of the George W. Bush administration in the United States, in contrast to use of education, law enforcement, economic aid, and other methods to prevent terrorism, led some analysts to include this war on terror as an example of collective violence.

Indirect effects of war and other military activities

Along with the direct impacts of war and other military activities on health, collective violence may also cause serious health consequences through its impact on the physical, economic, social, and biological environments in which people live. The environmental damage may affect people not only in nations directly engaged in collective violence, but also in all nations. Much of the morbidity and mortality during war, especially among civilians, has been the result of damage to the societal infrastructure, including destruction of food and water supply systems, healthcare facilities and public health services, sewage disposal systems, power plants and electrical grids, and transportation and communication systems. Destruction of infrastructure has led to food shortages and consequent malnutrition, contamination of food and drinking water and resultant food-borne and waterborne illness, and healthcare and public health deficiencies and resultant disease (Levy and Sidel 2008).

Preparation for war can also adversely affect human health. Some of the impacts are direct, such as injuries and deaths during training exercises, and others are indirect. As with war itself, preparation for war can divert human, financial, and other resources that otherwise might be used for health and human services.

Damage to the physical environment—water, land, and air—and extensive use of non-renewable resources may be the result of preparation for war as well as war itself. Lakes, rivers, streams and aquifers, land masses, and the atmosphere may be polluted through testing and use of weapons. Non-renewable resources are extensively consumed in weapons production, testing, and use.

The economic environment may also be adversely affected by the diversion of resources from education, housing, nutrition, and other human and health services to military activities and through an increase in national debt and/or taxation. These economic impacts affect both developed and developing countries. In our globalized world, armed conflict in one part of the world may have substantial impacts globally, such as in increases in oil and food prices.

Governmental and societal preoccupation with preparation for wars—often known as *militarism*—may lead to massive diversion of resources away from the promotion of human welfare. This

preoccupation may lead to policies that promote ‘pre-emptive war’ (when an attack is allegedly imminent) and to ‘preventive war’ (when an attack may be feared sometime in the future). Diversion of resources towards war-related activities is a problem worldwide, but is especially important in developing countries. Many developing countries spend substantially more on military expenditures than on health-related expenditures; for example, in recent years, Angola spent US\$196 per capita for military expenditures (in 2010) and US\$183 per capita for health (in 2008).

The social environment may be affected by increasing militarism, by encouragement of violence as a means for settling disputes, and violation of human rights and restriction of civil liberties. Preparation for war can also promote violence.

Another important indirect impact of war is the creation of many refugees and internally displaced persons: Many of the world’s 10.5 million refugees have left their native countries as a result of war. Refugees often flee to neighbouring less-developed countries, which are often already facing significant challenges in addressing the public health needs of their own populations. In addition, the vast majority of the 27.5 million internally displaced persons worldwide have left their homes to escape war. These internally displaced persons are often worse off than refugees who have left their countries because they frequently do not have easy access to food, safe water, healthcare, shelter, and other necessities.

Approximately 9.9 million of these internally displaced persons are in five countries: the Democratic Republic of Congo, Iraq, Somalia, Sudan, and Syria. Refugees and internally displaced persons experience much higher rates of mortality and morbidity, much of it due to malnutrition and infectious diseases. The vast majority of refugees and internally displaced persons as a result of war are women, children, and elderly people who may be highly vulnerable not only to disease and malnutrition, but also to threats to their security.

The environment may be disrupted during war or the preparation for war. Conventional weapons may damage the environment such that the health-supporting infrastructure—systems of food and water supply, sewage disposal, medical care and public health, power generation and supply, transportation, and communication—is severely disrupted or destroyed. Malnutrition of the affected population may increase the frequency and severity of infectious diseases. The biological environment may also be disrupted by the production, testing, and use of biological weapons. Ionizing radiation from the production, testing, use, and disposal of nuclear weapons and radioactive materials, such as depleted uranium, may also contaminate and damage the environment. So may the release of hazardous and toxic substances from damaged industrial facilities or from the production, testing, use, and unsafe disposal of chemical weapons.

Hazardous wastes from military operations represent potential contaminants of air, water, and soil. For example, groundwater was contaminated with trichloroethylene (TCE), a probable human carcinogen, and other toxins at the Otis Air Force Base in Massachusetts; 125 chemicals were dumped over a period of 30 years at the Rocky Mountain Arsenal in Colorado; and benzene, a human carcinogen, was found in extremely high concentrations at the McChord Air Force Base in the State of Washington (Westing 2008).

Both during war and the preparation for war, military forces consume huge amounts of fossil fuels and other non-renewable

materials. Energy consumption by military equipment can be substantial. For example, an armoured division of 348 battle tanks operating for 1 day consumes more than 2.2 million L of fuel and a carrier battle group operating for 1 day consumes more than 1.5 million L of fuel. The US military annually consumes millions of tons of fuel and emits huge amounts of carbon monoxide, oxides of nitrogen, hydrocarbons, and sulphur dioxide (Westing 2008).

Weapons systems

Conventional weapons

Conventional weapons consist of explosives, incendiaries, and weapons of various sizes, ranging from 'small arms and light weapons' to heavy artillery and bombs. Small arms and light weapons (SALW), which include pistols, rifles, machine guns, and other hand-held or easily transportable weapons, are the weapons most often used in wars. Although some restrictions have been placed on their use in war, such as the outlawing of the use of 'dum-dum bullets' (which cause extensive injuries when striking a human), there has been little effective effort to prohibit their use. In the Millennium Report of the United Nations (UN) Secretary-General to the General Assembly, Kofi Annan stated that small arms could be described as weapons of mass destruction because the fatalities they produce 'dwarf that of all other weapons systems—and in most years greatly exceed the toll of the atomic bombs that devastated Hiroshima and Nagasaki' (Annan 2000).

Conventional weapons have accounted for the overwhelming majority of adverse environmental consequences due to war. During the Second World War, for example, extensive carpet bombing of cities in Europe and Japan accounted not only for many deaths and injuries, but also for widespread devastation of urban environments. During the Persian Gulf War, the more than 600 oil fires in Kuwait accounted for widespread environmental devastation and respiratory ailments among people who were exposed to the smoke from these fires. The bombing of mangrove forests during the Vietnam War led to destruction of these forests, and the resultant bomb craters have remained several decades afterwards, often filling with stagnant water that serves as a breeding ground for mosquitoes transmitting malaria and other mosquito-borne diseases.

The international trade in small arms and light weapons fuels much collective violence, especially in developing countries. The UN General Assembly, in 2013, took a major step towards regulating the international trade in these conventional weapons by overwhelmingly approving the Arms Trade Treaty, which links purchases of arms to the human-rights records of the purchasing countries. The Treaty is designed to prevent exported weapons from contributing to human rights violations, terrorism, or organized crime, and to prohibit arms shipments that are deemed to be harmful to women or children.

Armed drones

Unarmed drone aircraft have been used for many years to conduct surveillance. Since 2004, the United States has been conducting armed drone strikes over Pakistan in an effort to kill people that it suspects of being terrorists. The US Central Intelligence Agency contends that its drone strikes have killed more than 600 militants in Pakistan since May 2010, but no non-combatant civilians.

However, the Bureau of Investigative Journalism at the City University in London has reported that most of the 1842 people who have been killed in more than 230 armed drone strikes in Pakistan since 2008 have been militants, but at least 218 of them may have been non-combatant civilians. In late 2011, a US citizen was killed by a targeted armed drone attack in Yemen. In early 2012, the US Attorney General asserted a right to kill US citizens in other countries who are plotting attacks against the United States.

Nuclear weapons

Nuclear weapons have become increasingly widespread since their development in the 1940s. There are now an estimated 19,000 nuclear warheads in at least nine nations—the United States, Russia, the United Kingdom, France, China, Israel, India, Pakistan, and North Korea (Stockholm International Peace Research Institute 2012). The United States currently has approximately 1000 nuclear war heads on alert on land-based intercontinental ballistic missiles (ICBMs) and submarine-launched ballistic missiles; Russia currently maintains 1200 war heads on alert, nearly all of which are on ICBMs.

The historic high in the explosive capacity of the global nuclear weapons stockpiles was reached in 1960 with an explosive capacity equivalent to 20,000 megatons (20 billion tons or 40 trillion pounds) of trinitrotoulene, or equivalent to that of 1.4 million of the nuclear bombs dropped on Hiroshima (Sutton and Gould 2008). In the United States in 1967, the nuclear stockpile had reached approximately 32,000 nuclear warheads of 30 different types. In 2012, the US stockpile was about 9400 warheads. Five thousand of the nuclear weapons in the United States, Russia, and possibly other countries are on 'hair-trigger' alert, ready to fire on a few minutes' notice.

The detonation of nuclear bombs over Hiroshima and Nagasaki in August 1945 during the Second World War led to the immediate deaths of approximately 200,000 people, primarily civilians, as well as to lasting injury and later death of many others, together with massive devastation—and widespread radioactive contamination—of the environment in these two cities (Sutton and Gould 2008). Atmospheric testing of nuclear weapons by the United States, the Soviet Union, and other countries also led to environmental contamination, with increased rates of leukaemia and other cancers among populations who were downwind from these tests. The effects of exposure to iodine-131 (a radioactive isotope of iodine produced by the testing) on children has been well documented (Institute of Medicine and National Research Council 1999). In addition to the potential for use of nuclear weapons by national armed forces, there is an increasing threat of their use by non-state actors.

From 1945 to 1990, the United States produced approximately 70,000 nuclear weapons; other nations also produced many of these weapons. Production of nuclear weapons has led to major environmental contamination (Levy and Sidel 2005). For example, the area around Chelyabinsk in Russia has been heavily contaminated with radioactive materials from the nuclear weapons production facility in that area. The level of ambient radiation in and near the Techa River in the area has been documented to be as high as 28 times the normal background radiation level (Burmistrov et al. 2006). Another example is the leakage of radioactive materials from the storage of wastes from nuclear weapons

production at Hanford, along the Columbia River in Washington State, leading to extensive radioactive contamination (Westing 2008).

The dismantling and disposal of nuclear weapons has also led to environmental contamination. The primary site for the disassembly of US nuclear weapons is the Pantex Plant, located 17 miles northeast of Amarillo in the Texas panhandle (Levy and Sidel 2005). Overall, the United States has dismantled more than 60,000 nuclear war heads since the 1940s; during the 1990s, 11,751 war heads were dismantled. Approximately 14,000 plutonium pits (hollow shells of plutonium encased in steel or another metal that are essential components of nuclear weapons) are in interim staging at Pantex (Levy and Sidel 2005). Plutonium, an element first produced in the Manhattan Project in 1942, has a half-life of 24,000 years. Plans to increase production capacity to 50 to 80 pits per year have been delayed because of budgetary reasons.

Radiological weapons

'Dirty bombs', consisting of conventional explosive devices mixed with radioactive materials, or attacks on nuclear power plants with explosive weapons could widely scatter highly radioactive materials. Another example of a radioactive substance used in weapons is depleted uranium (DU), uranium from which the uranium isotope usable for nuclear weapons or as fuel rods for nuclear power plants has been removed (Depleted Uranium Education Project 1997). DU is used militarily as a casing for armour-penetrating shells. An extremely dense material, uranium used as a casing increases the ability of the shell to penetrate the armour of tanks; uranium is also pyrophoric and bursts into flames on impact. DU-encased shells were used by the United States during the Persian Gulf War, the Iraq War, and the war in Kosovo; similar shells were used by the United Kingdom in the Iraq War. DU, which is both radioactive and extremely toxic, has been demonstrated to cause contamination of the soil and groundwater. Use of DU is considered legal by the nations that have used it, but its use is considered by other nations to be illegal under the Geneva Conventions and other international treaties.

Chemicals

A variety of chemical weapons and related materials have the potential for direct health effects during collective violence and also for contaminating the physical environment during war and the preparation for war. The potential for exposure exists not only for military and civilian populations, who may be exposed during the use of chemical weapons in wartime, but also for workers involved in the development, production, transport, and storage of these weapons and for community residents living near facilities where these weapons are developed, produced, transported, and stored. In addition, disposal of these weapons, including their disassembly and incineration, can be hazardous.

During the Vietnam War, the US military used defoliants on mangrove forests and other vegetation, which not only defoliated and killed trees and other plants, but may also have led to excessive numbers of birth defects and cases of cancer among nearby residents (Levy and Sidel 2005). In addition, development and production of conventional weapons involve the use of many chemicals that are toxic and can contaminate the environment. Furthermore, there is now a plausible threat of non-state agents using chemical weapons; a Japanese cult, Aum Shinrikyo, used

sarin in the subway system of two Japanese cities in the mid 1990s, accounting for the deaths of 19 people and injuries to thousands (Lee et al. 2012).

The Chemical Weapons Convention (CWC), which came into force in 1997, prohibits all development, production, acquisition, stockpiling, transfer, and use of chemical weapons. It requires each state party to destroy its chemical weapons and chemical weapons production facilities, as well as any chemical weapons it may have abandoned on the territory of another state party. The verification provisions of the CWC affect not only the military sector but also the civilian chemical industry worldwide through certain restrictions and obligations regarding the production, processing, and consumption of chemicals that are considered relevant to the objectives of the convention. These provisions are to be verified through a combination of reporting requirements, routine onsite inspection of declared sites, and short-notice challenge inspections. The Organization for the Prohibition of Chemical Weapons (OPCW) in The Hague, established by the CWC, ensures implementation of the provisions of the CWC. The disposal of chemical weapons required by the CWC has raised controversy about the safety of two different methods of disposal: incineration and chemical neutralization. The controversy about safety and protection of the environment has delayed completion of the disposal by the date required by the CWC.

Biological agents

These consist of bacteria, viruses, other microorganisms, and their toxins, which can not only directly produce illness in humans, but can also be used against other animals or plants, thereby adversely affecting human food supplies or agricultural resources and indirectly affecting human health. Biological agents have been used relatively infrequently during warfare, but there has long been a potential for their use. These agents have been used as weapons, albeit sporadically, since ancient times. In the sixth century BC, Persia, Greece, and Rome tried to contaminate drinking water sources with diseased corpses. In AD 1346, Mongols besieging the Crimean seaport of Kaffa placed cadavers of plague victims on hurling machines and threw them into Kaffa. In the mid-eighteenth century, during the French and Indian War, a British commander sent blankets infected with smallpox to Native Americans. During the First World War, Germany dropped bombs containing plague bacteria over British positions and used cholera in Italy. During the 1930s, Japan contaminated the food and water supplies of several cities and sprayed the cities with cultures of microorganisms.

Gruinard Island, off the coast of Scotland, was contaminated in 1942 by a test use of anthrax spores by the United Kingdom and the United States (Harris and Paxman 1962). During the 1950s and 1960s, secret large-scale open-air tests at the US Army Dugway Proving Ground may have introduced the microorganisms that cause Q fever and Venezuelan equine encephalitis into the deserts of Western Utah (Cole 1988). In 1979, the accidental release of anthrax spores near Sverdlovsk in the Soviet Union resulted in at least 77 cases of inhalation anthrax and at least 66 deaths (Meselson et al. 1994).

There is concern that biological agents could be used as terrorist weapons. In the autumn of 2001, anthrax spores were disseminated through the US mail, causing 23 cases of inhalational and skin anthrax, five of which were fatal. The Centers for Disease

Control and Prevention has identified three categories of diseases caused by biological agents, according to its level of concern that they may be used as terrorist weapons. Category A consists of the agents that cause anthrax, botulism, plague, smallpox, tularemia, and viral haemorrhagic fevers. Category B consists of the agents that cause brucellosis, glanders, melioidosis, psittacosis, Q fever, typhus fever, viral encephalitis, water safety threats, and food safety threats (such as *Salmonella* and *Shigella* species, and *Escherichia coli* O157:H7), as well as epsilon toxin of *Clostridium perfringens*, ricin toxin from castor beans, and staphylococcal enterotoxin B. Category C consists of the agents that cause emerging infectious diseases such as Nipah virus and hantavirus (Centers for Disease Control and Prevention 2012).

Antipersonnel landmines

Tens of millions of antipersonnel landmines are still deployed in 72 countries and seven disputed areas. These landmines have been termed 'weapons of mass destruction, one person at a time'. They have mostly been placed in rural areas, posing a threat to residents of these areas and often disrupting farming and other activities. Civilians are the most likely to be injured or killed by landmines, which injure or kill approximately 4000 people annually; the vast majority of landmine victims are civilians, primarily poor people living in rural areas. About one-quarter of landmine victims are children. It is estimated that half of all landmine victims die of their injuries before they reach appropriate medical care. Although a mine may cost only a few dollars to produce, it may cost more than US\$1000 to remove. And its adverse economic impact on human health and well-being is substantially higher. Mines, in addition to maiming and killing people, make large areas of land uninhabitable. Remaining in place for many years, they pose long-term threats to people, including refugees and internally displaced persons returning to their homes after long periods of war. Since the entry into force of the Anti-Personnel Landmine Convention in 1997, production of landmines has been markedly reduced, although 12 countries continue to produce antipersonnel landmines, including China, India, Pakistan, Russia, and the United States. Since 1997, millions of landmines that had been implanted in the ground have been removed (International Campaign to Ban Landmines n.d.). Many of the mines are still buried and additional resources will be required to continue unearthing and destroying them, tasks that pose inherent risks to demining personnel (Sirkin et al. 2008).

Weapons in space

The deployment of weapons in space represents another risk of weapons systems igniting armed conflict or adding to its potential health consequences. Attempts by the United Nations to limit weapons in space have thus far failed. In 2008, Russian and Chinese delegates to a UN conference presented a draft treaty banning weapons in space, but the United States opposed such a treaty. The risk of an arms race of weapons in space continues.

The role of public health in addressing war

War and the preparation for war have enormous adverse impact on humans and their environment. Public health workers have an important part to play in response to war. As the World Health Assembly declared in 1981, 'the role of health workers in

promoting and preserving peace is a significant factor for achieving health for all' (World Health Assembly 1981).

Prevention of war

The health and environmental problems created by collective violence can appear to be overwhelming. However, standard public health principles and implementation measures can be successfully applied in addressing these problems. The following subsection of this chapter highlights three standard public health approaches that can be developed and implemented in addressing these environmental problems: (1) surveillance and documentation, (2) education and raising awareness, and (3) advocacy for sound policies and programmes.

Surveillance and documentation

Much can be accomplished by undertaking surveillance and other activities to document the problems caused by war. Although the numbers of deaths, injuries, and diseases among uniformed combatants are generally well documented, deaths, injuries, and diseases among civilians are more difficult to document. Household cluster surveys have been used during the Iraq War to estimate the civilian casualties. Technical approaches to surveillance can include environmental monitoring as well as biological monitoring, the latter to document and assess the human burden of environmental contaminants and their adverse health consequences. Non-technical approaches can include information from physician reports, reports in the mass media, and assessments by government agencies.

Education and raising awareness

Much can also be accomplished by educating and raising the awareness of health professionals, policymakers, and the general public about the problems caused by war. A multifaceted approach that incorporates publications by citizens' groups and professional organizations, information in the mass media, and personal communication is often valuable. In addition, public health workers can assist people in distinguishing between accurate and inaccurate information and in setting priorities.

Advocacy for sound policies and programmes

Finally, much can also be accomplished by advocating for improved policies and programmes that help prevent collective violence and minimize its public health impact.

Levels of prevention

Those concerned with the promotion and protection of health classify preventive measures into four basic categories: pre-primary (primordial) prevention, primary prevention, secondary prevention, and tertiary prevention. Pre-primary prevention consists of measures to prevent adverse health consequences by removing the conditions that lead to them. Primary prevention consists of measures to prevent the health consequences of a specific illness or injury by preventing its occurrence in a specific individual or among members of a specific group. Secondary prevention consists of measures to prevent or limit the health consequences of an illness or injury, or to limit the spread of an infectious disease to others, after the disease process has begun. Tertiary prevention consists of efforts to rehabilitate those injured and to reintegrate

them into society or, in the case of prevention of collective violence, to prevent the resumption of violence.

Pre-primary prevention

In general, pre-primary (primordial) prevention requires political and social will. Pre-primary and primary prevention may be difficult to accomplish because the causes of the disease or injury may be unknown and, when they are known, the preventive methods may be difficult to implement technically or politically. As measures for pre-primary or primary prevention are usually more effective and rarely have negative consequences, they are generally considered preferable to secondary prevention, even when implementation is difficult or expensive. Secondary prevention is usually easier to implement politically and technically but, because such methods are often ineffective or only partially effective, they may create a false sense of security and encourage risk taking, can be more expensive than primary prevention, and many measures are more likely than pre-primary or primary prevention methods to have adverse consequences. The health consequences of war and the aftermath of war can be prevented or reduced through pre-primary prevention. This generally requires cooperation among civil society (non-governmental) organizations, governmental agencies, and organizations of health professionals.

The underlying causes of collective violence include poverty, socioeconomic inequalities, adverse effects of globalization, and shame and humiliation. Some of the underlying causes of war and militarism are becoming more prevalent or worsening.

Persistence of socioeconomic disparities and other forms of social injustice are among the leading underlying causes of war. The rich–poor divide is growing. In 1960, in the 20 richest countries, the per-capita gross domestic product (GDP) was 18 times that of the 20 poorest countries; by 1995, this gap had increased to 37 times. Inequality is not restricted to personal income, but includes other important areas of life, such as health status, access to healthcare, education, and employment opportunities. In addition, abundant national resources, such as oil, minerals, metals, gemstones, drug crops, and timber, have fuelled many wars in developing countries.

Globalization is similarly a two-edged sword. Insofar as globalization leads to good relations among nation-states and reductions in poverty and disparities within and among nations, it may play a powerful role in prevention of collective violence. Conversely, if globalization leads to exploitation of people, the environment, and other resources, it may cause war.

The Carnegie Commission on Preventing Deadly Conflict has identified the following factors that put nations at risk of violent conflict, including:

- ♦ Lack of democratic processes and unequal access to power, especially in situations where power arises from religious or ethnic identity and leaders are repressive or abusive of human rights.
- ♦ Social inequality characterized by markedly unequal distribution of resources and access to these resources, especially where the economy is in decline and there is, as a result, more social inequality and more competition for resources.
- ♦ Control by one group of valuable natural resources, such as oil, timber, drugs, or gems.
- ♦ Demographic changes that are so rapid that they outstrip the capability of a nation to provide basic necessary services and opportunities for employment (Carnegie Commission on Preventing Deadly Conflict 1998).

The United States and other developed nations must increase funding for humanitarian and sustainable development programmes that address the root causes of collective violence, such as hunger, illiteracy, and unemployment.

Promoting multilateralism

Since its founding in 1946, the UN has attempted to live up to the goal stated in its charter: ‘To save succeeding generations from the scourge of war’ (United Nations, 1945). Its mandate, along with preventing war, includes protecting human rights, promoting international justice, and helping the people of the world to achieve a sustainable standard of living. Its affiliated programmes and specialized agencies include, among many others, the United Nations Children’s Fund (UNICEF), the WHO, the Food and Agriculture Organization (FAO), the International Labour Organization (ILO), the United Nations Development Programme (UNDP), and the Office of the UN High Commissioner for Refugees (UNHCR). These UN-related organizations, and the UN itself, have made an enormous difference in the lives of people.

The UN spends about US\$5 billion a year. By comparison, annual global military expenditures—more than US\$2 trillion—would pay for the entire UN system for about 400 years.

The UN has no army and no police. It relies on the voluntary contribution of troops and other personnel to halt conflicts that threaten peace and security. The United States and other member states on the Security Council decide when and where to deploy peacekeeping troops. Long-term conflicts fester while conflicting national priorities deadlock the UN’s ability to act. In fact, if stymied by the veto, the UN has little power beyond the bully pulpit.

Ending poverty and social injustice

Poverty and other manifestations of social injustice contribute to conditions that lead to collective violence (Levy and Sidel 2013b). Growing socioeconomic and other disparities between the rich and the poor within countries, and between rich and poor nations, also contribute to the likelihood of armed conflict. By addressing these underlying conditions through policies and programmes that redistribute wealth within nations and among nations, and by providing financial and technical assistance to less-developed nations, countries such as the United States can minimize poverty and other forms of social injustice that lead to collective violence.

Creating a culture of peace

Public health workers can do much to promote a culture of peace, in which non-violent means are utilized to settle conflicts. A culture of peace is based on the values, attitudes, and behaviours that form the deep roots of peace. They are in some ways the opposite of the values, attitudes, and behaviours that promote collective violence, but should not be equated with just the absence of war. A culture of peace can exist at the level of the family, workplace, school, community, state, and the world. Public health workers and others can play important roles in encouraging the development of a culture of peace at all these levels.

The Hague Appeal for Peace Civil Society Conference was held in 1999 on the 100th anniversary of the 1899 Hague Peace Conference. The 1899 conference, attended by governmental representatives, was devoted to finding methods for making war more humane. The 1999 conference, attended by 1000 individuals and representatives of civil society organizations, was devoted to finding methods to prevent war and to establish a 'culture of peace'. The document adopted at the 1999 conference, the Hague Appeal for Peace and Justice for the twenty-first century, has been translated by the UN into all its official languages and distributed widely around the world. Its ten-point action agenda addressed education for peace, human rights, and democracy; the adverse effects of globalization; sustainable and equitable use of environmental resources; elimination of racial, ethnic, religious, and gender intolerance; protection of children; reduction of violence; and other issues.

Primary prevention

Primary prevention includes preventing specific elements of collective violence and sharply reducing preparation for war, as follows.

Strengthening nuclear weapons treaties

Unlike the implementation of treaties banning chemical weapons and biological weapons, there is no comprehensive treaty banning the use or mandating the destruction of nuclear weapons. Instead, a series of overlapping incomplete treaties has been negotiated. The Partial Test Ban Treaty (PTBT) of 1963, promoted in part by concerns about radioactive environmental contamination, banned nuclear tests in the atmosphere, under water, and in outer space. The expansion of the PTBT, the Comprehensive Nuclear-Test-Ban-Treaty (CTBT), a key step towards nuclear disarmament and preventing proliferation, was opened for signature in 1996 but has not yet received sufficient signatures or ratifications to enter into force. It bans nuclear explosions, for either military or civilian purposes, but does not ban computer simulations and subcritical tests, which some nations rely on to maintain the option of developing new nuclear weapons. As of late 2012, the CTBT had been signed by 183 nations and ratified by 157. Entry into force requires ratification by the 44 nuclear-capable nations, of which 36 had ratified it by late 2012. The following nuclear-capable nations had not ratified it: China, Egypt, India, Iran, Israel, North Korea, Pakistan, and the United States.

The Treaty on the Non-Proliferation of Nuclear Weapons (the 'Nuclear Non-Proliferation Treaty', or NPT) was opened for signature in 1968 and entered into force in 1970. By late 2012, a total of 189 states parties (nations) had ratified the treaty. The five nuclear weapon states recognized under the NPT—China, France, Russia, the United Kingdom, and the United States—are parties to the treaty. The NPT attempts to prevent the spread of nuclear weapons by restricting transfer of certain technologies. It relies on a control system carried out by the International Atomic Energy Agency (IAEA), which also promotes nuclear energy. In exchange for the non-nuclear weapons states' commitment not to develop or otherwise acquire nuclear weapons, the NPT commits the nuclear weapon states to good-faith negotiations on nuclear disarmament.

Every 5 years since 1970 the states parties have held a review conference to assess implementation of the treaty. The International Court of Justice (the World Court) in 1996 in an advisory opinion urged that the nations possessing nuclear weapons move expeditiously towards nuclear disarmament, as is required by Article VI of the NPT.

The United States should help stop the spread of nuclear weapons by actively supporting and adhering to these treaties, and by setting an example for the rest of the world by renouncing the first use of nuclear weapons and the development of new nuclear weapons. It should work with Russia to dismantle nuclear war heads and increase funding for programmes to secure nuclear materials so that they will not fall into the hands of non-state actors.

Increasing attention is being focused on the elimination of nuclear weapons. Policymakers, such as former US Secretaries of State Henry Kissinger and George Shultz and former military leaders, have called for measures towards the elimination of these weapons (Shultz et al. 2007). One measure that may accomplish this is a nuclear weapons convention comparable to the Chemical Weapons Convention, the Biological and Toxin Weapons Convention, and the Anti-Personnel Landmine Convention. In 2007, Costa Rica and Malaysia submitted to the UN an updated draft of a nuclear weapon convention, modelled after the Convention on Chemical and Biological Weapons as well as the International Treaty on Anti-Personnel Landmines. The proposed convention which supplements existing international treaties, such as the NPT and CTBT, if adopted, would prohibit nations from pursuing or participating in the development, testing, production, stockpiling, transfer, use, and threat of use of nuclear weapons. Nations possessing nuclear weapons would need to destroy their nuclear arsenals, vehicles to deliver nuclear weapons would also be destroyed or converted to non-nuclear weapon uses, and production of weapons-usable fissile material would be prohibited.

Strengthening the Chemical Weapons Convention

The CWC is the strongest of the arms control treaties outlawing a single class of weapons. Inspection and verification of compliance with its provisions lies in the hands of the Organization for the Prohibition of Chemical Weapons (OPCW) in The Hague, established by the CWC (Lee et al. 2012). Controversies about safety and protection of the environment during the disposal of chemical weapons required by the CWC have delayed completion of the disposal, and large stockpiles still remain in a number of the world's nations that pose a continuing threat to health and to the environment.

Strengthening the Biological and Toxin Weapons Convention

Although the development, production, transfer, or use of biological weapons was prohibited by the 1975 Biological and Toxin Weapons Convention (BWC), several nations are believed to retain stockpiles of such weapons. The verification measures included in the BWC are weak and attempts to strengthen them have been unsuccessful. The United States has blocked attempts to strengthen the verification measures of the BWC, announcing that such measures might lead to exposure of US industrial or military secrets. All nations should support strengthening of

the BWC and should refrain from secret activities, often termed *defensive* that may fuel a biological arms race.

Perhaps even more important, global public health capacity to deal with all infectious disease must be strengthened. Significant vulnerabilities to persistent global reservoirs of endemic illness in impoverished and underserved populations could lead to future pandemics. The best individual and collective efforts at diagnosing and treating disease outbreaks can be overwhelmed by any natural or intentionally induced epidemic. Consequently, support for strong global preventive public health capabilities provides the best ultimate defence against infectious disease threats.

Promoting the support of the Anti-Personnel Mine Ban Convention (the Ottawa Treaty)

As of late 2012, a total of 160 nations were parties to this 1997 convention. Thirty-six nations had neither signed nor ratified it, including China, India, Iran, Israel, Russia, and the United States. Resources are needed to clear the millions of landmines that are deployed.

Secondary prevention

The consequences of collective violence can also be prevented or diminished by secondary prevention if war occurs, by preventing deaths and injuries among military personnel and civilians, by preventing environmental destruction, and by seeking an end to the war. Secondary prevention methods include strengthening adherence to the Geneva Convention and other treaties that lessen the effects of war; reducing military activities, including preparation for war; and negotiating effective treaties to lessen environmental damage.

Tertiary prevention

Critical measures after an armed conflict include rehabilitating and reintegrating those living with disabilities due to the conflict; repairing the damage to the physical, social, cultural, and economic environments; and preventing further conflicts. Tertiary prevention methods include programmes for physical and social rehabilitation for individuals, groups, and communities; provision of appropriate aid to communities and nations damaged by collective violence, such as the Marshall Plan after the Second World War; environmental remediation; and the establishment of truth and reconciliation commissions, such as in South Africa after Apartheid.

The role of non-governmental organizations

Non-governmental organizations (NGOs) can be potentially important partners for public health workers in preventing and alleviating the consequences of collective violence. These *civil society organizations* focus on war from a medical and public health perspective by:

- ◆ Intervening to mitigate the consequences of armed conflict.
- ◆ Researching the effects of war.

- ◆ Educating the public and decision-makers about the impact of war on health and the environment.
- ◆ Advocating for changes in global attitudes and policies concerning war and for changes concerning the most dangerous weapons and practices of war (Loretz 2008).

Some NGOs provide direct humanitarian assistance to the victims of collective violence. These organizations generally participate in secondary and tertiary prevention, but some, such as the International Committee of the Red Cross, have also begun to play a role in primary prevention. Humanitarian assistance organizations may also play a role in primary prevention of violence. They may be strong advocates for civilian populations among whom they live and to whom they provide humanitarian assistance (Waldman 2008).
